Stress inhibits the release of hypothalamic-pituitary-gonadal axis hormones, alters the onset of puberty, impairs reproductive behavior, suppresses lactation, and adversely affects diverse aspects of parental care. The specific mechanisms that produce these outcomes are not well understood. A role for endogenous opioids is indicated by the observation that the stress-induced suppression of hypothalamic-pituitary-gonadal axis hormones is blocked by the administration of the opiate receptor antagonist naloxone. Other studies suggest that the stress-induced inhibition of reproduction occurs through nonopioidergic mechanisms and that hypothalamic-pituitary-adrenal axis hormones mediate these antireproductive effects.

Immunology

Stressful conflicts, the disruption of relationships, and the formation of new social groups impair immune responses in primates. Glucocorticoid levels within the range normally achieved in response to stress suppress numerous aspects of immunity, including lymphocyte numbers, lymphocyte function, and *in vivo* antibody responses to antigenic challenges. An alternative pathway for these immunological effects is through the catecholaminergic innervation of the lymph nodes, thymus, and spleen.

Health Disorders and Disease

Primate models provide evidence for adverse stress effects in coronary heart disease, susceptibility to upper respiratory infections, and vulnerability to simian acquired immune deficiency syndrome (the primate homolog of AIDS). Sustained exposure to stress induces metabolic abnormalities that parallel those found in humans who develop abdominal obesity and early-onset diabetes. Stress exacerbates the effects of high dietary salt intake on hypertension in baboons. Sustained exposure to stress elicits changes in primate behavior and neurobiology that resemble features of human anxiety disorders, alcoholism, and major depression.

Environmental and Genetic Risk Factors

Stress is an inescapable aspect of life that cannot be eliminated nor avoided for long. Equally obvious is that certain individuals are particularly vulnerable to

stress, whereas others seem unscathed. Experimental studies of primates indicate that environmental and genetic risk factors contribute to individual differences in vulnerability and resilience.

Prenatal Development

Pregnant squirrel monkeys and rhesus macaques exposed to chronic sources of stress produce infants with deficits in muscle tone, impaired neuromotor coordination, and shortened attention spans. Increased secretion of cortisol induced in mothers by the administration of exogenous ACTH during mid-gestation results in neonatal outcomes similar to those produced by prenatal stress. Later in life, prenatally stressed monkeys, and monkeys derived from ACTH-treated mothers, exhibit exaggerated neuroendocrine responses to stress and deficits in immune physiology.

Postnatal Development

Rhesus macaque infants raised without mothers show prolonged and inappropriate responses to stress, self-directed emotional behavior, diminished norepinephrine neurotransmission, altered autonomic reactivity, and impaired immune responses. Neuronal changes in dendritic branching have been characterized in motherless monkeys, and selective alterations in tyrosine hydroxylase activity are evident in the striatum, substantia nigra, and ventral tegmental area. Attempts to rehabilitate motherless monkeys may partially ameliorate anomalies in behavior but allegedly fail to normalize neurobiological effects.

Early-Life Stress Inoculation

Severely stressful early experiences increase the risk for the development of adult psychiatric conditions, including depression and anxiety disorders. Far less researched, but of equal importance, is the suggestion that mild forms of stress, instead of increasing vulnerability, result in subsequent stress resistance. Various descriptions of inoculating, immunizing, steeling, toughening, or thriving, the notion that mild early-life stress reduces vulnerability to subsequent stressors has important implications for understanding the neurobiology and prevention of mental health disorders. Recent studies of monkeys suggest that early exposure to mild stress leads subsequently to diminished measures of anxiety, pro-social tendencies, enhanced cognitive control, larger prefrontal brain volumes, and attenuated activation of the hypothalamic-pituitary-adrenal axis.

Social Buffering

The deleterious effects of stress on immune physiology are often buffered or reduced by the presence of familiar companions in primates with social proclivities.

Under certain conditions, familiar companions likewise buffer or reduce the stress-induced secretion of glucocorticoids. Although glucocorticoids are known to regulate immune processes involved in susceptibility to disease, there is limited evidence in primates to implicate glucocorticoids as a direct mediator of social stress-buffering effects.

Phylogenetic Constraints

Species differences in neuroendocrine, autonomic, and behavioral responses to stress are important concomitants of species-typical modes of interacting with social and nonsocial environments. Interspecies differences in stress physiology and emotional vulnerability are well documented for two New World primates (squirrel monkeys and titi monkeys) and for at least five different species of macaques.

Inherited Variation

Coping with stress is increasingly recognized as key feature of health. Stimulated by the concept of primary prevention, health professionals are developing programs aimed at teaching people how to cope effectively with stress. That modes of coping are learned and not inherited from others is implicit in this approach. Yet human twin studies clearly suggest robust hereditary influences on aspects of coping with stress. Individual differences in autonomic reactivity to stress and cerebrospinal fluid levels of neurotransmitter metabolites are likewise heritable in rhesus macaques. High heritabilities for total brain size have been reported in humans and monkeys, but little is known about the genetics of inherited variation in stress-related corticolimbic brain circuits.

Nonhuman Primate Models of Early Stress
Gene by Environment Interaction

Glossary

Gene by environment interaction

Describes how a phenotype (e.g., impulsive behavior) is the result of both genetic and non-genetic (environmental) factors such that the influence of an environmental effect is conditioned by the individual's genotype.

Hypothalamic-pituitary-adrenal (HPA) axis

The hypothalamus, pituitary gland and adrenal cortices form a linked neuroendocrine system (axis) that controls an organism's reaction to stress through the secretion and regulation of a hormonal cascade. Activation of the HPA axis

Rearing

induces the release of CRH (corticotropin-releasing hormone) from the hypothalamus, ACTH (adrenocorticotrophic hormone) from the pituitary gland and glucocorticoid hormones (in primates, cortisol) from the adrenal cortex.

Refers to the practice of raising captive laboratory animals under specific experimental conditions including (1) "mother-reared", or (2) "nursery-reared" in which subjects are permanently removed from their mothers within days of birth, after which the infant may be placed with age-matched peers (peer-rearing), or raised on an inanimate surrogate mother. Rhesus macaques (*Macaca mulatta*) are a species of Old World Monkey with broad indigenous distribution from eastern Afghanistan to Eastern China. They live in gregarious, hierarchical social groups centered on a core of related lines of females. Rhesus are the most common laboratory primate in the United States.

Rhesus macaque

On the basis of the available evidence from human studies, it is well established that stress early in life, particularly during infancy and early childhood, is a significant predictor and risk factor for a range of developmental, neurological, and behavioral deficits, often including autism-like behaviors. Some deficits manifest early in life, resulting in children who are fearful and anxious, socially withdrawn, or exhibit inappropriate and aggressive play behavior. These adverse experiences and impoverished environments in early human childhood are also known to greatly increase the risk of long-term neurobiological effects on systems essential for normal emotional growth, social competence, and appropriate development of neuroendocrine responsivity. It is clear that experience-based brain development in the very early years of life sets biological pathways that affect cognition, behavior (e.g., anxiety and aggression), capacity to learn, memory, and physical and mental health throughout the life cycle. The hypothalamic-pituitary-adrenal (HPA) axis is exceptionally vulnerable to the effects of early life stress, and such perturbations are suspected of playing a major role in the etiology of affective disorders, mood disorders, and other psychopathologies in adulthood. Delineating the proximal causal links among early experience, brain development, and normative and dysfunctional social behavior is a major goal. Although many questions remain, these biological pathways are becoming increasingly better understood, due largely to evidence that early stressful experience reduces neural plasticity and may lead to the permanent silencing of genes critical to the regulation of the stress response to stress experienced later in life.

Nonhuman Primate Models of Early Stress

Nonhuman primates are a remarkably important model for exploring and ultimately attempting to understand the impact of early stress and trauma on the developing brain, its effects on individual differences in temperament and psychopathology, and the potential interaction of these factors with underlying genetic differences that may impart resilience or vulnerability to early stress. In most primate species, particularly those with gregarious and hierarchical social organization such as rhesus macaques (*Macaca mulatta*), infants are nurtured and protected by their mothers and extended female relatives during their first years. They spend most of their first few months in direct physical contact with their mothers, and even a brief separation can elicit robust behavioral, neuroendocrine, and neurobehavioral activation in both mother and infant.

Studies using animal models such as rodents and nonhuman primates have enabled researchers to address experimentally the effects that early traumatic experiences and impoverished environments can have on a multitude of behavioral and physiological parameters. Early stress and trauma can be defined in a number of ways, but principally they include abuse and neglect of the infant and also may include stress or illness in the mother both pre- and postnatally. In the laboratory, early stress and trauma are modeled most commonly by manipulating the conditions under which infants are reared. The first studies investigating the impact of early adverse experiences were focused on the effects of permanent separation of the infant from its mother – a paradigm initiated by Harry Harlow in the 1960s. Variations of the maternal separation paradigm grew to examine the effects of surrogates on maternally deprived infants and the effects of varying exposure to like-aged peers, but all models emphasized the permanent separation of an infant from its mother.

Although these experiments revealed the devastating consequences of maternal deprivation, they nevertheless represent intense manipulations of early social and emotional experience. As such, they may not appropriately capture the less tangible effects on brain development resulting from the kinds of parental neglect and abuse reported in human clinical populations that increase the risk for adult onset psychopathologies. Alternatively, or in addition to, permanent maternal deprivation are studies investigating the effects of acute, periodic, or repeated mother–infant separations followed by reunion. Compared to the severe social and emotional deficits associated with permanent maternal deprivation, infants that experience short-term maternal separation exhibit more subtle impacts on neuronal and behavioral development. Regardless, long-term physiological and behavioral effects result, including alterations to the HPA axis and in stress reactivity. Indeed, infant monkeys exposed to repeated separations from their mothers show pronounced and persistent behavioral and physiological activation. These experiments in nonhuman primates are more likely to reflect the forms of stressful, unpredictable, and traumatic experiences that neglected and abused children may experience and suggest how such early trauma can affect the normal development of neuronal pathways and neural structures, as well as neuroendocrine responsivity.

Gene by Environment Interaction

The nonhuman primate model is also well suited for studying the interplay between heritable genetic

differences between individuals and their response to nongenetic, environmental insults, that is, gene by environment interaction. Compared to rodents, nonhuman primates such as rhesus macaques are closely related to humans, and this is evident in the degree of similarity between human and rhesus gene sequences of common behavioral candidate genes. At the same time, captive laboratory primates share tightly controlled housing conditions that help to limit the number of intangible, nongenetic variables, which are difficult to isolate in human studies. Finally, most psychopathology involves deficits in appropriate emotional and social functioning, and the complex social organization and behavioral repertoires of nonhuman primates approximate far more closely those of human subjects than do other laboratory animals.

Recent efforts to understand the interaction between genetic and nongenetic (environmental) factors that underlie interindividual differences in response to stress and trauma have focused on functional polymorphisms in genes that are thought to play an important role in mediating response to stress or to be influenced by the effects of early stress and trauma. One of the better-known examples comes from the serotonin system. Serotonin is an important neurotransmitter involved in the regulation of mood and affect, and perturbations in serotonergic neurotransmission, whether naturally occurring or induced, are thought to result in a host of emotional and behavioral disorders in humans. Serotonin is critical for the development of the central nervous system (CNS) during the early postnatal period when mother–infant bonds are cemented. Moreover, serotonergic neurotransmission is involved in the activation and feedback control of the neuroendocrine stress axis, and the activation of stress hormones is known to regulate gene expression, including the serotonin transporter gene (5-HTT).

Both the rhesus macaque and human versions of the serotonin transporter gene contain a complex length polymorphism in the gene's promoter region in which the shorter (s) of the two common alleles reduces transcriptional efficiency. The s allele in humans is associated with numerous mood and psychiatric disorders, including anxiety and depression, harm avoidance, and aggression-related traits. In a recent human longitudinal study, serotonin transporter gene variation increased the risk of depressive symptoms in individuals who had stressful, impoverished childhood experiences. In rhesus macaques, several studies have demonstrated an interaction between the s allele of the serotonin transporter and permanent and acute maternal separation on (1) cerebrospinal fluid measures of 5-hydroxy-3-indoleacetic acid (5-HIAA), a marker of central serotonergic

neurotransmission; (2) neonatal measures of motor coordination, reflex, and orienting ability and temperament (thought to be sensitive measures of CNS growth and maturity in the developing brain); and (3) HPA axis activation. In all cases, the effects of serotonin genotype were evident in maternally separated monkeys (but not in maternally raised monkeys), with persistent, lasting effects into adulthood on affective behaviors.

The monoamine oxidase A gene (MAOA), a common candidate gene in human psychiatric genetics involved in metabolizing serotonin, dopamine, and norepinephrine, also contains a functional length polymorphism in the regulatory region that is conserved across humans and rhesus macaques. As with the serotonin transporter gene, the association between high- and low-activity alleles and aggressive behavior was dependent on whether subjects had been raised by their mothers. That is, the effect of functional variation in MAOA was conditioned by early rearing experience.

Although early traumatic and stressful experiences in infancy and childhood have demonstrated effects on a wide range of downstream emotional, behavioral, and neurobiological deficits, it is also clear that not all individuals exposed to early life stress undergo such deficits. The nonhuman primate model for early stress and trauma provides an experimental vehicle for controlled hypothesis-driven analyses that have begun to delineate the complex interactions between early stress and normal gene variation and their effects on brain and CNS function. Yet the specific and causal links between genes and environment, and their interactions on neuronal growth and development in the infant brain, remain poorly understood. As such, there is a continued need for clinical and population studies in humans and in nonhuman animal model systems such as primates to elucidate the complex interplay of heritable predisposition and experience on brain development and function.

Scope of the Problem

Prison Inmates

Prison Staff

Limitations and Conclusion

Glossary

<i>Bullying</i>	The act of repeatedly intimidating a weaker person by the real or threatened infliction of physical, verbal, or emotional abuse.
<i>Role conflict</i>	A form of social conflict that takes place when the person is forced to take on two different and incompatible roles at the same time.
<i>Depersonalization</i>	A feeling of detachment or estrangement from the self, in which the individual senses a loss of personal identity.
<i>Punitive approach</i>	The perspective on incarceration which reflects the belief that inflicting punishment on an individual will act as a deterrent and decrease the likelihood of the crime being repeated.
<i>Rehabilitative approach</i>	The perspective on incarceration which reflects the belief that an individual can be retrained to function appropriately in society through supportive educational programs in prison.

Scope of the Problem

In 2005, 714/100 000 U.S. residents were incarcerated in prisons and jails, a rate that had risen by 5.0% over the previous 5 years. Bureau of Justice statistics in the United States indicate that if current incarceration rates remain unchanged, an estimated 1 out of every 20 people (5.1%) will serve time in prison during his or her lifetime. U.S. incarceration rates are very much higher than in Europe, where there are wide variations between countries. Southern European countries have a relatively low rate of 80/100 000, compared with 184/100 000 in eastern and central Europe; rates in the United Kingdom fall in the middle, at 139/100 000 in 2005.

There is a very much higher incarceration rate among men than women, and more than 90% of convicts are men. However, one important change over recent years has been the rate of growth of the number of female inmates, which has outstripped that of men. The U.S. female prison population grew by 5.0% annually from 1999 to 2004, compared with a growth rate of 3.3% in the male population. Research has not kept pace with this change, and until recently most studies were conducted on the male inmate population. Overall, inmates are more likely to be young, single, and less well educated than the population at large. Ethnic minority groups are substantially overrepresented in the prison population. In 2004, 12.6% of Black American males in their late twenties were incarcerated, compared with 3.6% of Hispanic males and 1.7% of White males.

Imprisonment is one of the most stressful human experiences and figures high in all comparisons of negative life events. A combination of environmental

and personal deprivation in unpleasant and often frightening circumstances can lead to the perception of extreme stress. Factors such as adherence to a strict daily routine, close living proximity, loss of control over life course, and loss of freedom have all been identified as causing psychological distress. Interpersonal relationships with prison officers and other inmates and the strain on relationships with friends and family are also causes of psychological disturbance. Associated factors such as financial hardship, coping with guilt, and dealing with aggressive fellow inmates can contribute to stress-related problems in prisoners.

Prison staff also report a range of stressors associated with the job. The main stressors are the maintenance of order and the risk of loss of control over hostile inmates, combined with the lack of support from supervisors and society. The difficulty in balancing the responsibility for the welfare of prisoners with the responsibility for security leads to conflicting work demands.

Prison Inmates

Sources of Stress

A number of studies have identified a range of stressors reported among inmates. These fall into several categories.

Personal relationships The separation from partner and family has been cited as one of the main stressors of serving time in prison. For female inmates, the separation from their children is particularly stressful. The majority of women in prison are mothers and many are also heads of households. The separation from their children has been found to be associated with a wide range of feelings such as guilt, anxiety about welfare of the children, and fear of losing close attachments to the children. This may be one reason why women have been found to suffer more emotional distress in prison than men.

The effects of separation are also evident from the finding that married men show higher levels of distress than single men. Being deprived of intimacy and worrying about the welfare of their family are also significant. The lack of confiding relationships and being denied meaningful contact with the opposite gender may create new anxieties regarding sexual identity. Coming to terms with such a mixture of emotions can pose a risk to mental health.

Establishing friendships within prison is an important aspect of adaptation. One study of young inmates found that social support and the ability to confide in

friends in prison were major predictors of psychological well-being. The fear of rejection by other inmates and social isolation can cause heightened anxiety, especially in the initial stages of incarceration. However, in many cases such concerns are ill-founded because one study found that prisoners tend to receive more social support from other prisoners than they had anticipated.

Economic factors The loss of income associated with incarceration can be a major problem for prisoners and their families. Men who report financial hardship experience greater distress than those who are financially secure.

Prison environment Lack of privacy and crowding are serious problems within the prison environment. In many countries, prisons are filled beyond capacity. In the United Kingdom, for example, the Home Office released figures in 2005 that indicated a 106% occupancy rate across all prison service establishments. When personal space is threatened, angry or defensive reactions may result. Research has shown that men living in single cells report liking their accommodation more and perceive themselves having greater control than inmates living in multiple occupancy cells or dormitories. Violence is a serious concern for many inmates, and many have long-lasting fears of attack that may be associated with sustained neuroendocrine and autonomic activation. The rates of sexual and physical assault are difficult to estimate because much abuse goes unreported. Bullying and favoritism by staff are also found in many institutions.

Other aspects of the prison environment that can be sources of stress are noise levels, lack of control over lighting, physical discomfort arising from extremes of heat and cold, lack of contact with the natural environment, absence of intellectual stimulation, and constraints on physical activity.

One issue that is problematic is the pressure not to show evidence of distress. Often emotions associated with stress such as fear, grief, and depression are not admitted and are hidden from staff and other inmates. This hinders the analysis and solution of stress-related problems.

Time Course of Imprisonment

Certain sources of stress are more evident at different stages of imprisonment. Three phases of a prisoner's career have been identified.

Initial phase This is the most stressful period when the inmate first encounters prison life. First-time

offenders are particularly vulnerable due to the loss of liberty and separation from friends and family. This stage is often characterized by feelings of denial followed by anxiety and depression, although other emotions such as shock, fear, isolation, grief, and anger are also reported frequently. The adjustment period typically lasts for the first 4–6 weeks of confinement. It is at this stage that many suicide attempts are made.

Middle phase During the middle stage of the sentence, the focus is on the prison community. Friendships are established, and some inmates experiment with drugs and gay sex. Mandatory drug testing has been introduced in many countries; despite efforts to prevent the importation and use of illegal drugs into prisons, the problem is common. In 2001, a UK prison survey found that 19% of inmates reported using cannabis in the previous month, and 13% reported using opiates. Although drug use is prevalent, a smaller proportion of inmates use drugs while in prison than did prior to incarceration.

Final phase Some convicts become preoccupied with their release in the final few weeks of their prison terms. Apprehension about cultural changes after long sentences is coupled with worry about the attitudes of friends and neighbors and the need to reestablish family relationships and reenter employment. Health and economic disparities that existed before incarceration are intensified following release, because access to jobs, health insurance, public housing and health benefits may be limited to ex-prisoners, particularly in the United States, and disproportionately in ethnic minority groups. Thus incarceration continues to exert effects leading to increased stress and poor health even after release.

Responses to the Stress of Prison Life

The stress experienced by prisoners has been measured in several ways: by self-report measures of mood, well-being, and mental health; by the incidence and prevalence of physical health outcomes, mental health outcomes, and physiological indicators of stress; and by the most powerful indicator of hopelessness and despair, suicide.

The investigation of the psychological state of inmates and stress-related effects in prisons faces a number of methodological challenges. First, assessing the impact of incarceration is complicated by limited knowledge about the prior health and well-being of inmates. Many studies of stress in prisons that use outcomes such as hospitalization for mental illness

during incarceration are problematic in that incident psychopathology, that is, new onset mental illness, may be difficult to distinguish from prevalent psychopathology, which has been consistently demonstrated as having higher rates in prisoners. Longitudinal studies following prisoners from the first days of incarceration are the only way of studying the emergence of stress resulting from the prison environment rather than ongoing stress from psychosocial disadvantage or existing psychopathology that entails greater risk of conviction in the first place.

Second, the general population is a poor comparison group when assessing the relative prevalence of stress-related disorder in prisoners. Many individuals sent to prison have histories of psychological problems and drug abuse prior to sentencing. Inmates also tend to come from low-income families, to be unemployed, and to have limited education and therefore may have previously encountered negative life events, inadequate health care, and poor living conditions. Drug and alcohol problems frequently precede incarceration; a survey of convicts in state prisons in the United States indicated that 50% of those convicted of violent crimes were under the influence of drugs or alcohol at the time of the offense, and in 1993 drug offenders accounted for 61% of inmates in federal prisons. The high prevalence of some problems among inmates cannot, therefore, be attributed to the prison experience and is confounded by considerable preexisting psychosocial disadvantage in this group.

Nevertheless, anxiety, depression, and complaints of fatigue, sleeplessness, headache, and backache are common. In one study of female convicts, nearly half met the diagnostic criteria for posttraumatic stress disorder (PTSD), and major depression was more prevalent than in the general population. A study of a representative sample of imprisoned juvenile delinquents in California found that half experienced PTSD, with many having witnessed or been involved in traumatic violent episodes. The prevalence of infectious disease, sexually transmitted disease, and tuberculosis is also high compared with the general population. Substantial weight gain has been recorded among female inmates, resulting from the combination of the sedentary lifestyle and the availability of energy-dense high-fat foods. A recent British study investigating subjective health status in female inmates addressed the confounding by lower socioeconomic status in prisoners. Using a comparison group of women from lower-socioeconomic-status sectors of the community, a comparable level of physical health complaints and a greater level of mental health complaints were found in prisoners.

Blood pressure has been found to be elevated in prison inmates compared with matched controls and to increase with the duration of confinement and the degree of crowding in prison. One particularly impressive study used a quasi-experimental approach by measuring the blood pressure of male convicts assigned to individual cells, four-bed cells, and larger dormitories in a medium-security prison. Blood pressure increased to a greater extent in men who were transferred to multiple-occupancy cells and dormitories compared with those who were transferred to other individual cells.

However, a third methodological problem with studies of physiological stress markers is that prison studies have not kept pace with recent advances in measuring such markers as ambulatory blood pressure, cortisol, catecholamines, and inflammation. One notable exception is the Copenhagen Solitary Confinement study, which assessed changes in mood, orientation, and serum cortisol during the first 3 months and compared prisoners kept in solitary confinement (SC) with prisoners in shared cells. Although anxiety, depression, and morning cortisol levels were reduced over time in the non-SC group, such reductions did not occur in the SC group, indicating a lack of adaptation to the prison environment. Many physiological markers of stress are good prognostic indicators of health problems such as autoimmune and cardiovascular diseases, and therefore it may be fruitful to pursue this avenue.

International surveys have found that the suicide rate in prison is between 3 and 11 times greater than that of the general population, with a reported fivefold increase compared with the UK general male population from 1978 to 2003. Most suicides take place within the first few weeks of incarceration and are more common in crowded institutions than other prisons. High rates have been recorded among prisoners on remand and those convicted of murder and serving life sentences. Although suicide is most frequent in young males, self-harm is highly prevalent in female inmates, and recent UK Home Office statistics report a rate of 58.7%. Unlike the pattern in the general population, depression is not a common diagnosis at the time of death, although about one-third of male suicides had some form of psychiatric treatment in the past. Drug or alcohol dependence can be found in a substantial proportion of these cases.

There is also evidence for a European trend toward reinstitutionalization of those with mental health problems in recent years – but in prisons rather than in psychiatric hospitals. A systematic review of prevalence studies in Western countries in 2002 found an overall prevalence of 3.7% for psychotic disorders (10% for major depression), representing a two- to

fourfold increase in mental illness compared with the general population. It is likely that U.S. prisons and jails hold up to twice as many individuals with mental illness than do state psychiatric hospitals; the prison system is not well equipped to support these individuals.

Characteristics of the Individual Convict

Some individuals adapt to incarceration better than others and survive even lengthy prison terms without experiencing high levels of distress. Older convicts tend to have more friends in prison, to have more contact with family and friends outside, and to report greater psychological well-being than younger individuals. A recent UK Home Office report, however, drew attention to the often overlooked but growing population of prisoners aged 60 and over. Although physical health problems in this cohort are often well provided for, psychiatric problems, in particular major depression, are not well treated. Political demand for longer sentencing for some crimes means that this older cohort will continue to provide an ongoing challenge for prison services. As noted earlier, higher levels of anxiety and depression are found in female than in male prisoners, although it is not clear whether this is a specific response to imprisonment or reflects the more general difference in distress found in the adult population at large. Members of ethnic and religious minorities suffer more than members of the majority because prejudice and cultural isolation are added to the other sources of stress present in prison.

In the United States, it has been noted that White prisoners are more likely to attempt and complete suicide than African American prisoners, but the reasons are poorly understood. One suggestion is that being raised in the tough conditions experienced by many African Americans makes adults more resilient to the pressures of prison life. Alternatively, because proportionately more Black than White Americans are incarcerated, they may come from a broader spectrum of society; White inmates may include a higher proportion of marginalized, psychologically vulnerable individuals.

Methods of Reducing Stress among Inmates

The management of stress in prison inmates involves several different levels of intervention. Medical and psychiatric services have an important role in preventing suicide and self-harm, in managing drug dependence, and in treating other psychiatric and neurological problems. Support is often hampered by the reluctance of inmates to divulge personal information to authorities or to reveal weakness. Training prison staff more generally in suicide prevention

is also important. A recent public health initiative in Texas prisons led to improvements in health outcomes, and Telemedicine, allowing rapid access to telephone consultations for physical and mental health problems, proved to be a novel and effective way of delivering health care.

At a more general level, education, training, and other initiatives help build prisoners' self-esteem and confidence in their ability to adapt to civilian life after release. Increasing physical activity and exercise may also be beneficial. Studies have found that inmates who have a job detail or are on work-release programs show less evidence of stress than those who are not active.

Finally, changes at the institutional level may be warranted. It is likely that modifications of prison regimes in relation to aspects such as staff attitudes, privileges, training opportunities, and relocation of inmates to serve their terms near their families could play a key role in alleviating stress among inmates. However, the reality is that stress does not figure highly among the concerns of prison administrators or politicians, some of whom would argue that prison should be stressful.

Prison Staff

Sources of Stress

Research on prison staff members finds that many of the issues cited in the general literature on occupational stress are relevant for them as well. As with other jobs, factors such as work demands, role conflict, low control, and poor social support emerge as relevant. Thus, symptoms of psychological distress and job dissatisfaction are greater among correctional officers who report high work demands coupled with low control and low support from management and colleagues.

However, these problems are exacerbated by the peculiar requirements of working in prison. Prison officers cite the conflict of responsibilities in the job as an underlying source of stress and dissatisfaction. On the one hand, prison staff members are responsible for the welfare of inmates and for the maintenance of their physical and psychological well-being. On the other hand, they are required to maintain security and protect the public from the dangerous and sometimes violent convicts. The prison environment is often volatile, with a high risk of aggressive behavior from inmates. Confrontations with inmates and the threat of physical danger are cited as major sources of stress, irrespective of the age and gender of staff members. Ethnic minority prison officers have been found to experience lower stress levels, especially in the

United States, where ethnic minorities are grossly overrepresented among inmates.

Some differences have been observed between new and long-serving staff. Newly appointed staff members report a lack of support from supervisors and a concern with lack of control over the working environment as particularly problematic. Those who have been working for longer periods are more troubled by the absence of support and respect from society and the lack of variation in the job. The combination of tedium associated with mundane day-to-day activities and the pressure to maintain vigilance in order to react quickly to high-risk incidents appears to be especially stressful.

Many prison officers believe that the responsibilities for security and the welfare of inmates are incompatible obligations. A recent meta-analysis of factors predicting work-related stress revealed an interesting effect of punitive versus rehabilitative attitudes – officers in the United States who endorsed rehabilitative attitudes experienced greater stress, whereas those in Canada with stronger punitive attitudes were more stressed. This suggests that when individuals' beliefs about their role are at odds with the ethos of the prison service in a particular country, stress and conflict are the result.

Outcomes of Stress

High rates of sick leave for both minor complaints (fatigue, headaches, and indigestion) and physical health problems (high blood pressure and peptic ulcers) occur among prison staff. In one study, the rates of coronary heart disease, hypertension, and ulcers were found to be greater among correctional officers than a comparable sample of police officers. The divorce rate in correctional officers is reported as being twice that of blue- and white-collar workers in general. Job dissatisfaction is coupled with the increased prevalence of divorce in this occupational group. The rates of sick leave are greater among staff members in maximum security prisons and in prisons with many drug users than in other correctional institutions.

There is a greater prevalence of psychological distress in prison officers. Much of the research has focused on burnout, with male and female staff members reporting similar high levels of depersonalization and emotional exhaustion. Self-reported anxiety and depression are also elevated compared with the general working population. Female officers are more likely to take sick leave than male officers, but this pattern may result from family demands rather than different levels of stress at work.

Methods of Reducing Stress in Prison Staff

It has been noted in the research literature that many prison officers do not perceive themselves to be stressed but, rather, see their colleagues as being stressed. Pressure not to show the effects of stress may be particularly evident in a male-dominated environment where there is fear that any sign of weakness will be exploited by the inmates. Admitting to feeling stressed may be interpreted as an inability to cope and therefore as not being strong enough for the job at hand. Alternatively, some prison officers may not be able to identify the personal effects of stress in themselves. This suggests that education about stress and how it can be managed may both benefit prison staff members directly and help them to identify the repercussions of stress in inmates.

A number of studies have found that exercise and fitness programs have positive effects. One investigation involving a 6-week strength and aerobic program showed reductions in body weight, skinfold thickness, and cholesterol levels, together with beneficial changes in smoking, alcohol consumption, sleep, nutritional habits, and stress tolerance.

Consultation and efforts to enhance social support at work have been found to counteract the effects of stress. Factors such as goal consensus among staff, a proactive management style, and increasing of decision latitude can be incorporated into the working environment.

Limitations and Conclusion

There are a number of limitations in the studies that have been carried out thus far about stress in prisons. Most have been cross-sectional in nature, identifying associations between aspects of prison experience and diminished well-being, and the causal sequence is uncertain. Longitudinal designs and data on inmates prior to imprisonment are important in the assessment of the impact of stressors because some apparent effects of incarceration may be the direct consequences of prior experience. The nature of the offense, family situation, and previous physical and mental health are all important factors that should be taken into account. Also, the civilian groups with which prisoners are compared in many studies may not be matched appropriately in terms of background characteristics.

The generalizability of results across populations is uncertain. The majority of studies have been conducted on White male adults and may not be relevant to women, ethnic minorities, and juveniles. This is

not mere tokenism because it is apparent from the limited information available that the experience of prison is very different for people of different backgrounds and cultures. The applicability of findings to different prison systems must also be questioned. Justice systems in the United Kingdom and other European countries differ greatly from the U.S. system, and countries also vary in the extent to which individuals with serious psychiatric histories are found in prison. The application of management suggestions derived from one system must be reviewed carefully before their implementation elsewhere.

Nevertheless, the data do indicate that imprisonment is severely stressful for many inmates and that work within the prison system is also associated with higher rates of stress-related dysfunction than comparable jobs. Education and the implementation of specific stress-management programs may be beneficial to both groups and may help ensure that stress in prison is confined within tolerable limits.

Mortality, Physical Morbidity, and Cognitive Impairment
Psychological Morbidity
Etiological Factors
Summary

Glossary

<i>Physical morbidity</i>	Illness and hospital admissions.
<i>Psychological morbidity</i>	Anxiety, depression, posttraumatic stress disorder, and psychiatric admissions.

Mortality, Physical Morbidity, and Cognitive Impairment

Mortality

There have been relatively few studies of physical health and mortality in prisoners of war (POWs) and controls; studies from different countries have produced different findings. The largest series of studies is based on a cohort of U.S. World War II Pacific, European, and Korean POWs and controls assessed by a series of researchers. In the early postwar years, there was increased mortality in all POW groups, due largely to tuberculosis (TB) and postwar trauma. By 1965, no increased mortality appeared in European POWs. Mortality was still increased in Pacific POWs, due to cirrhosis, tuberculosis, and trauma, and in Korean veterans, due to trauma. This increased mortality in Pacific and Korean POWs had persisted for 9 and 13 years, respectively, postwar, whereas death from cirrhosis of the liver had increased from the tenth year of follow-up. In an Australian study of POWs of the Japanese in the 1950s, more deaths from suicide, trauma, cirrhosis, and TB were initially reported. In an Australian controlled cohort study (40 years postwar), no increase in mortality in POWs was found.

Physical Health and Hospital Admissions

In U.S. POWs from all three theaters, general hospital admission rates to 1965 were increased significantly. However, in a 40-year follow-up of a subsample,

no increased rates of hypertension, diabetes, or myocardial infarction were found. A full medical examination of the Australian cohort revealed no differences in current medical disorders. Higher rates of peptic ulcer were, however, generally found in World War II POWs and in U.S. naval POWs in Vietnam; the latter also experienced excessive disorders of the peripheral nervous system.

Thus, postwar peptic ulcer, trauma, TB, and cirrhosis appear more common in World War II POWs than in combatant controls. Although mortality appears to be increased in the U.S. studies, there may have been sampling biases; findings from a well-matched Australian cohort study suggested no difference.

Cognitive Impairment

U.S. World War II and Korean prisoners of war High- and low-weight-loss POWs have been compared with combatant controls. Cognitive impairment (memory and learning) was greatest in POWs with the greater weight loss; there was, however, little difference between low-weight-loss POWs and their controls.

Australian prisoners of war of the Japanese No significant differences in the Australian cohort follow-up (50 years postwar) were found between POWs and combatant controls using detailed psychometric tests; high- and low-weight-loss groups similarly did not differ on any tests or on prevalence of clinically diagnosed dementia. These similarities occurred despite POWs having a greater incidence of depression that could have impaired their psychometric performance, a factor that may have accounted for the positive findings in U.S. studies, which relied on volunteers. Finally, in the same cohort, POWs and controls did not differ on any neuropsychological tests or on brain width (using cerebral X-ray computed tomography, CT, scan); however, POWs, interestingly, had a shorter mean anteroposterior brain diameter. Taking into account methodological problems of some studies, cognitive impairment is not confirmed in POWs postwar.

Psychological Morbidity

Minnesota Multiphasic Personality Inventory Questionnaire Studies (U.S. World War II and Korean Prisoners of War)

U.S. World War II prisoners of war Minnesota Multiphasic Personality Inventory (MMPI) symptom profiles (depression, anxiety, and somatic concern)

were elevated (from highest to lowest) in POWs with chronic posttraumatic stress disorder (PTSD), POWs recovered from PTSD, POWs with other psychiatric diagnoses, POWs with no psychiatric disorder, and normal men. The personality profiles of denial and suppression were also elevated.

Korean prisoners of war and combatant controls Hypochondriasis, depression, hysteria, psychasthenia, paranoia, and ego strengths distinguished the POWs and the controls. The MMPI assesses both personality and psychological symptoms. It shows some unexpected personality differences in POWs and controls, presumably because the personality subscales are sensitive to change in mood. The Eysenck Personality Questionnaire (a more stable measure) showed no differences when used in other Australian POWs and controls.

Psychiatric Admissions and General Psychological Morbidity Data

U.S. prisoners of war (World War II and Korea) Hospital admission rates were significantly higher in the Pacific POWs for 27 of the 33 somatic conditions studied and for all nine of the psychiatric diagnoses, whereas in Korean POWs, admissions were elevated in only nine somatic conditions and three psychiatric conditions. Admission rates in the European POWs were not increased. Bias was possible due to a response rate of only 59% for the initial medical questionnaire. Again, 45 years postwar these POWs had moderately elevated rates of hospitalization and depressive disorders and greatly elevated PTSD; no difference was found in bipolar disorder, schizophrenia, alcoholism, or physical health.

Australian World War II prisoners of war of the Japanese These POWs (88% response) were no more likely to have had psychiatric admissions than combatant controls and indeed had fewer postwar multiple psychiatric admissions. Diagnosed clinical anxiety and major depression in POWs were twice that of controls; alcohol abuse and psychosis were no different. These findings were consistent with their significantly higher scores on questionnaire measures of anxiety and depression. Surprisingly, 10 years later there had been a significant decline in both diagnosed clinical anxiety and depression.

General psychological morbidity is elevated significantly for many years postwar; however, admission data findings vary between U.S. and Australian POWs.

Posttraumatic Stress Disorder

World War II and Korea

U.S. prisoners of war This group has been studied extensively by Engdahl and colleagues and by Sutker

and colleagues. Initial questionnaires were returned by only 35% of the sample surveyed; some 500 of these were then studied 40 years postwar with a 75% response. In the first series of 426 POWs, the rate of PTSD was increased greatly and lifetime prevalence of depression was increased moderately, but bipolar disorder, schizophrenia, and alcoholism were not. In 262 of this sample, 53% met the criteria for lifetime PTSD and 29% for current PTSD; in Japanese POWs, the rates of PTSD were higher, 84% lifetime and 59% current PTSD prevalence. In 62 of the World War II POWs, 50% had PTSD within 1 year of release and 29% has PTSD 40 years later. A lifetime diagnosis of generalized anxiety was found in over 50%. In another study of 915 of the original World War II cohort, 53% of POWs initially responded and 188 of these were interviewed. Sixty-seven percent of this sample had PTSD; 50% had shown no recovery, 24% had some residual symptoms, 39% had mild symptoms, and 29% had fully recovered. It is important to note the possibility of considerable sample selection bias in this series of studies (due to poor response rates), which may have inflated the rates of psychiatric morbidity.

The second U.S. series of studies are those of Sutker and colleagues. Korean and Pacific veterans ($n = 326$) had experienced more extreme trauma and had the highest prevalence rates for lifetime and current mental disorders, including PTSD. In a small subsample, 77% of the Pacific POWs had current PTSD and 78% a lifetime diagnosis, compared with 18 and 29%, respectively, in controls. In Korean POWs, PTSD symptoms were found in 90–100%. Finally, World War II aviators were less likely to have PTSD than nonaviators. The sample bias was also probable in these studies because the subjects were selected from attenders at a Veteran's Administration (VA) medical center. Other studies have used questionnaires to assess PTSD with similar high prevalence rates in military and civilian POWs.

Canadian prisoners of war Higher rates of PTSD and other symptoms were found in POWs from Europe 50 years postwar, whereas in former Far East POWs, 30% had current PTSD 50 years postwar and 90% had at least one PTSD symptom.

Australian prisoners of war In the Australian cohort, no subjects appeared to meet full *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed. (DSM-III) criteria for PTSD 40 years postwar, although a majority of the sample had some PTSD symptoms and 50% had a clinical affective disorder or anxiety. At a further follow-up 10 years later, 4% of subjects had been diagnosed as having PTSD using DSM-IV criteria; there was, however,

a significant decline in psychiatric disorders overall, from 50 to 36%.

French and German prisoners of war of the Russians Forty years postwar, 71% of a selected sample (response 40%) had symptoms consistent with PTSD, whereas in a randomly selected subsample, the frequency of individual PTSD symptoms ranged from 84% (for recurring dreams) to 18% (for panic symptoms).

Dutch Resistance Veterans Sample veterans were studied 40 years postwar (76% response); half had been imprisoned and half had not. Interestingly, 54% of both groups had PTSD and a similar rate of other psychological symptoms. Paradoxically, this study followed an earlier study showing that, 15 years postwar, imprisoned Dutch resistance fighters had less incidence of psychiatric disorders than those not imprisoned.

There is little doubt that significant rates of PTSD are found long after the war, although not in all samples; the very high rates of PTSD found, particularly in U.S. samples, may be due in part to various forms of sampling bias.

Other Conflicts

Israeli prisoners of war of the Yom Kippur War POWs, combatants (who had experienced combat stress reactions), and normal combat veterans were compared; the prevalence of PTSD more than 18 years postwar in the three groups was 23, 37, and 14%, respectively, whereas current PTSD prevalence was 13, 13, and 3%. Psychophysiological complaints were also more frequent among POWs, as were trauma-related and general psychiatric symptoms. In terms of coping, those with high sensation-seeking qualities adjusted better to the stress of captivity and had fewer PTSD or other psychiatric symptoms; active coping strategies were used by high sensation seekers, whereas low sensation seekers used detachment and denial. In general, poor psychological adjustment was associated with more helplessness, more suffering, and less active coping, as well as hostility and ambivalence.

British prisoners of war from the Persian Gulf War In POWs studied both 6 and 18 months postwar, psychological symptoms (using the General Health Questionnaire, GHQ) reduced significantly; a poorer psychological outcome was associated with POWs witnessing physical violence and self-perceived deterioration in physical and mental health during captivity.

Balkan prisoners of war In Croatian POWs, 36% had postwar psychiatric disorder; camp conditions contributed to psychiatric symptoms (particularly threats against family members); however, group cohesion diminished the level of disorder. In another sample, only 4.5% met the full criteria for PTSD, 28% had no PTSD symptom cluster, and the remainder had some PTSD symptoms.

Comorbidity of Psychiatric Disorders in Prisoners of War

In one selected sample of Korean POWs, PTSD was found the most; depressive comorbidity occurred in 75%, anxiety in 45%, and alcohol abuse in 20%.

In the other U.S. series, of 262 World War II and Korean POWs (who had sought mental health treatment), 53% met the criteria for lifetime PTSD; 29% of those with PTSD had other axis I disorders. In a subsample, depression and anxiety coexisted in 61% of the sample. Depression was found in 10% of those without PTSD, in 23% of those with recovered PTSD, and in 61% of those with ongoing PTSD. The Australian POW study also found that anxiety and depression coexisted in a significant portion of the sample.

Etiological Factors

The severity of the stressful experiences of POWs differed in different theaters. Both Korean and Vietnam POWs were interrogated, brain-washed, and tortured, whereas Vietnam POWs were also kept for long periods in solitary confinement. POWs of the Japanese suffered gross physical deprivations, malnutrition, random brutality, hard physical labor, major physical illness, and ultimately a high mortality rate. European theater POWs did not suffer as severely, although resistance fighters (such as the Dutch) had a similar experience to Holocaust survivors. The POW experience in more recent conflicts has generally been briefer and less brutal. Studies addressing etiology have been somewhat piecemeal; World War II POWs provide the most consistent findings.

World War II Prisoners of War

In U.S. POWs, studied by Engdahl and colleagues, generalized anxiety and depressive disorders were related to captivity severity; preexisting psychopathology and family history of psychiatric disorder were not predictive. Chronic depression was predicted by a younger age at time of capture, lower education, more medical symptoms during captivity, and poorer social supports after release. Specific

captivity stressors (weight loss, torture, and disease during captivity) correlated strongly with psychological morbidity and PTSD, whereas age and education were protective. These findings have been largely replicated in the other U.S. series of studies by Sutker and in Canadian, French, and Australian POWs.

Vietnam Prisoners of War

Captivity trauma was greater in POWs captured before 1969 and was associated with more subsequent psychiatric morbidity. Aviators were more resilient to captivity than nonaviators; this was attributed to their higher educational status and military rank and better personal resources. Furthermore, there was no particular coping style indicative of psychiatric illness in this group. Paradoxically, still-serving POWs reported that the harshness of the war experience was associated with a belief of having actually benefited from imprisonment.

The severity of the captivity experience, especially as manifest in gross physical hardship and deprivation, predicted the subsequent short- and long-term psychological morbidity.

Summary

The POW experience varied according to the theater of war; the Japanese were particularly brutal captors. In the early postwar years, excess physical morbidity and mortality occurred particularly in Pacific POWs. Although this declined subsequently, deaths from cirrhosis showed a delayed increase.

Significant psychiatric morbidity has been the most consistent finding in all the studies, including conflicts since World War II, and morbidity has persisted for many years postwar. Studies in the United States have focused specifically on PTSD and show very high rates of prevalence, but sampling bias may, to some degree, contribute to their particularly high rates. Other anxiety disorders and depression are also increased, but psychoses are not. The comorbidity of disorders is common. Furthermore, the high rates of psychological disorder correlate with a range of indices of captivity severity, whereas some sociodemographic factors seem protective. Former POWs who served their countries well and suffered terribly

continue to live with the legacy of the inhumanity of their captors during war.

Glossary

<i>Effective solutions</i>	Coping responses that achieve one's problem-solving goals, but that also simultaneously maximize positive consequences (i.e., benefits) and minimize negative consequences (i.e., costs).
<i>Problems</i>	Specific existing or anticipated situations that demand responses for adaptive functioning, but that are not met by effective coping responses from the person confronted by them due to the presence of certain obstacles (e.g., ambiguity, uncertainty, conflicting demands, lack of resources, or uniqueness).
<i>Problem orientation</i>	The set of relatively stable cognitive-affective schemas that represent a person's generalized beliefs, attitudes, and emotional reactions about problems in living and one's ability to successfully cope with such problems.
<i>Problem-solving style</i>	The core cognitive-behavioral activities that people engage in when attempting to cope with problems in living.
<i>Social problem solving</i>	The cognitive-behavioral process by which individuals view the nature of problems in living and direct their attempts at coping with such stressors.
<i>Solution</i>	A coping response designed to alter the nature of the problematic situation, one's negative emotional reactions to it, or both.

Social Problem Solving

Throughout history, psychologists and philosophers have argued that an essential part of being human is the capacity to solve problems. Perhaps the most important idea emanating from this belief is the notion that problem-solving ability contributes significantly to social competence and overall psychological well-being, as the ability to cope with and resolve everyday stressful problems has been found to be strongly related to overall personal and social functioning.

Training individuals to become better problem solvers in order to facilitate their ability to cope with stressful situations has been referred to in the psychotherapy and counseling literature as social problem-solving therapy in order to highlight the social and interpersonal context in which real-life problem solving occurs. Social problem solving is defined as the cognitive-behavioral process by which individuals view the nature of problems in living and direct their attempts at coping with such stressors. Relevant problem-solving therapy (PST) goals broadly include altering the stressful nature of the situation itself (e.g., overcoming obstacles to a personal goal), changing one's reactions of distress to such problems (e.g., acceptance that a goal cannot be reached), or both.

Problems can be single events (e.g., obtaining a loan from a bank), a series of related problems (e.g., continuous arguments with a spouse), or chronic situations (e.g., a major chronic illness, such as cancer). Situations become problems when effective responses are required in order for the person to cope adaptively, but when such responses are not immediately available or identifiable due to the presence of various obstacles, including ambiguity, unpredictability, conflicting demands, deficient skills, or lack of resources.

Solutions are coping responses designed to alter the nature of the problematic situation, one's negative emotional reactions to it, or both, whereas effective solutions are those coping responses that not only achieve such goals, but also simultaneously maximize positive consequences (i.e., benefits) and minimize negative effects (i.e., costs).

The Problem-Solving Process

Problem-solving outcomes are largely determined by two general but partially independent dimensions – problem orientation and problem-solving style. Problem orientation is the set of relatively stable

cognitive-affective schemas that represent a person's generalized beliefs, attitudes, and emotional reactions about problems in living and one's ability to successfully cope with such problems. Problem orientation can be either positive or negative. A positive orientation is one that involves a tendency to appraise problems as challenges, be optimistic in believing that problems are solvable, perceive one's own ability to solve problems as strong, and believe that successful problem solving involves time and effort. Conversely, a negative problem orientation is one that involves the tendency to view problems as threats, expect problems to be unsolvable, doubt one's own ability to solve problems successfully, and become frustrated and upset when actually faced with problems.

Problem-solving style refers to those core cognitive-behavioral activities that people engage in when attempting to cope with problems in living. Three differing styles have been identified, one that is adaptive, while the other two reflect maladaptive ways of coping. Rational problem solving is the constructive problem-solving style that involves the systematic and planful application of certain specific skills, each of which makes a distinct contribution toward the discovery of an adaptive solution or coping response in a problem-solving situation. Rational problem solving involves the following four skills: problem definition and formulation, generation of alternatives, decision making, and solution implementation and verification. The goal of problem definition and formulation is to delineate the reasons why a given situation is a problem (e.g., the presence of obstacles), as well as to specify a set of realistic goals and objectives to help guide further problem-solving efforts. The purpose of the generation of alternatives task is to create, using various brainstorming principles, a large pool of possible solutions in order to increase the likelihood that the most effective ideas will be ultimately identified. The goal of decision making is to conduct a systematic cost-benefit analysis of each alternative by identifying and then weighing their potential positive and negative consequences if carried out, and then, based on this evaluation, to develop an overall solution plan. Finally, the purpose of solution implementation and verification is to carry out the solution plan, monitor and evaluate its effectiveness, and troubleshoot if the outcome is unsatisfactory.

Two additional problem-solving styles have been identified, both of which are dysfunctional or maladaptive in nature. An impulsive/careless style involves a generalized response pattern characterized by impulsive, hurried, and careless attempts at problem resolution. Although the individual characterized by this style actively attempts to apply various strategies to address problems, such attempts are narrow, hurried,

or incomplete. For example, a person with this style is likely to consider only a few solution alternatives, often impulsively implementing the first idea that comes to mind. In addition, the narrow range of options and their consequences are scanned quickly, carelessly, and unsystematically.

Avoidance style is a second maladaptive problem-solving pattern, this one characterized by procrastination, passivity, and overdependence on others to provide solutions. This type of individual generally avoids problems rather than confronting them head on, puts off addressing problems for as long as possible, waits for problems to resolve themselves, and attempts to shift the responsibility for solving his or her problems to other people. In general, both styles lead to ineffective or unsuccessful problem resolution.

Problem-Solving Deficits

Important differences have been identified in individuals characterized as effective versus ineffective problem solvers. In general, when compared to their effective counterparts, ineffective problem solvers report a greater number of life problems, more health and physical symptoms, more anxiety, more depression, and more psychological maladjustment. In addition, a negative problem orientation has been found to be associated with negative moods under routine and stressful conditions in general, as well as pessimism, negative emotional experiences, and clinical depression. Persons with a negative orientation also tend to worry and complain more about their health.

In addition, problem-solving deficits have been found to be significantly related to poor self-esteem, hopelessness, suicidal risk, self-injury, anger proneness, increased alcohol intake and substance risk taking, personalities difficulties, criminal behavior, alcoholism, secondary physical complications among persons with spinal cord injuries, premenstrual and menstrual pain, physical health problems, diminished life satisfaction, physical problems among adult cancer patients, and pain severity among adult cardiac patients.

Problem Solving as a Moderator of Stress

How people cope with stressful experiences, including major events (e.g., undergoing a divorce, dealing with the death of a spouse) and daily problems (e.g., continued arguments with a co-worker, limited financial resources) can, in part, determine the degree to which they will experience long-lasting psychological distress, particularly depression. Continued successful attempts at problem resolution will lead to a reduction or minimization of immediate emotional

distress and a reduced likelihood of long-term negative affect (i.e., clinical depression). Alternatively, if one's problem-solving coping skills are ineffective, or if extreme emotional distress impacts negatively on one's coping efforts, resulting in reduced motivation, inhibition of problem-solving performance, or both, then the likelihood of long-term emotional distress will be increased. Further, such negative outcomes can lead to the exacerbation of existing problems and the creation of new ones, which in turn can lead to another major stressful life event, and so forth. As such, how one copes with problems can lead to either an escalation or attenuation of the stress process. For example, research has demonstrated that under similar levels of high stress, individuals with poor problem-solving skills experience significantly higher levels of depression and anxiety than persons characterized by more effective problem-solving skills, supporting the notion that problem solving serves to attenuate the negative effects of stress.

Efficacy of PST

If effective problem-solving skills serve as an important buffering factor regarding the stress process, training individuals in such skills should lead to a decrease in emotional distress and improvement in overall psychological functioning. In fact, PST has been shown to be effective in a wide range of clinical populations, psychological problems, and the distress associated with chronic medical disorders. These include unipolar depression, geriatric depression, distressed primary care patients, social phobia, agoraphobia, obesity, coronary heart disease, adult cancer patients, schizophrenia, mentally retarded adults with concomitant psychiatric problems, HIV risk behaviors, drug abuse, suicide, childhood aggression, and conduct disorder.

In addition to its applicability to a variety of patient populations, PST also appears to be flexible with regard to treatment goals and methods of implementation. For example, it can be conducted in a group format, on an individual and couples basis, and as part of a larger psychosocial intervention package, and can be delivered by telephone. It can also be applied as a means of helping patients to overcome barriers associated with successful adherence to other medical or psychosocial treatment protocols.

PST Training Guidelines

Specific PST therapy objectives include (1) enhancing individuals' positive orientation and application of the four rational problem-solving tasks, and (2) minimizing their negative orientation and tendency to

engage in dysfunctional problem-solving style activities (i.e., impulsive or careless attempts to cope with problems; avoidance of problems). PST interventions include didactic explanations, training exercises, practice opportunities, and homework assignments geared to foster practice between training sessions.

Problem Orientation

Training in this problem-solving component is geared to facilitate the following: positive self-efficacy beliefs (the perception that people can improve their quality of life through effective coping and problem solving), beliefs that problems are inevitable (accepting the notion that it is common and normal to experience a wide range of problems), the ability to identify problems accurately when they occur, and the ability to inhibit emotional reactions that can lead to impulsive reactions or avoidance.

A variety of training approaches can be used to foster a positive problem orientation. One technique is the reverse advocacy role-play strategy. According to this strategy, the therapist pretends to adopt a particular belief about problems and asks the patient to provide reasons why that belief is irrational, illogical, incorrect, or maladaptive. Such beliefs might include the following statements: "Problems are not common to everyone; if I have a problem, that means I'm crazy," "There must be a perfect solution to this problem," "I'll never be the same again." At times when the patient has difficulty generating arguments against the therapist's position, the counselor then adopts a more extreme form of the belief, such as "No matter how long it takes, I will continue to try and find the perfect solution to my problem." This procedure is intended to help patients identify alternative ways of thinking and then to dispute or contradict previously held negative beliefs with more adaptive perspectives.

Patients are also taught to use feelings or emotions as cues that a problem exists by using visual images of a red traffic stop sign as a signal to stop and think. In essence, patients are taught to recognize various situations as problems and to label them as such. Accurately labeling a problem as a problem serves to inhibit the tendency to act impulsively or automatically in reaction to such situations. It also facilitates the tendency to approach or confront problems, rather than to avoid them.

Problem Definition and Formulation

Problem definition can be likened to mapping a guide for the remainder of the problem-solving process. The major focus of this task is to better understand the nature of the problem and to set clearly defined and

reasonable goals. In other words, locating a specific destination on a map makes it easier to find the best route to get there. Training in problem definition and formulation focuses on the following five specific tasks: gathering all available information about the problem, using clear and unambiguous language, separating facts from assumptions, identifying the factors that make the situation a problem, and setting realistic problem-solving goals.

Generation of Alternatives

When generating alternative solutions to a problem, PST encourages broad-based, creative, and flexible thinking. In essence, patients are taught various brainstorming strategies (e.g., the more the better, defer judgment of ideas until a comprehensive list is created). This helps to increase the likelihood that the best or most effective solution ideas will be discovered.

Decision Making

Once a list of alternative options has been generated, the problem solver begins to systematically and thoroughly evaluate the potential for each solution to meet the defined goal(s). Training in this component helps the patient to use the following criteria to conduct a cost-benefit analysis based on the utility of each alternative solution: the likelihood that the solution will meet the defined goal, the likelihood that the person responsible for solving the problem can actually carry out the solution plan optimally, personal (i.e., effects on oneself) and social (i.e., effects on others) consequences, and short- and long-term effects.

Solution Implementation and Verification

This last rational problem-solving task involves first carrying out the solution plan and then monitoring and evaluating the consequences of the actual outcome. PST encourages the patient to practice the performance aspect of solution implementation as a means of enhancing the probability that it will be carried out in its optimal form. Once the plan is under way, the patient is encouraged to monitor the actual results. Using this information allows the individual to evaluate the results by comparing the actual outcome with his or her expectations or predictions about the outcome.

Supervised Practice

After the majority of training has occurred, the remainder of PST should be devoted to practicing the newly acquired skills and applying them to a variety of stressful problems. Beyond actually solving stressful problems, ongoing in-session practice serves

three additional purposes: the patient can receive professional feedback from the therapist, increased facility with the overall PST model can decrease the amount of time and effort necessary to apply the various problem-solving tasks with each new problem, and practice fosters maintenance and generalization of the skills.

The number of practice sessions required after formal PST training often is dependent upon the competency level a patient achieves, as well as on the actual improvement in his or her overall quality of life. In the research protocols that have found PST to be an effective cognitive-behavior therapy intervention, the number of included sessions has ranged from 8 to 12.

Glossary

<i>Catabolism</i>	A wasting process.
<i>Dopamine</i>	A catecholamine neurotransmitter that mediates nerve signaling in the central nervous system.
<i>Opiergic compounds</i>	Opiates or compounds that have an opiate-like effect, for example, morphine, methadone, and heroin.
<i>Prolactin (PRL)</i>	Polypeptide produced in the pituitary with somatolactotropic actions, essential for the preparation of the breast during pregnancy and to assure postpartum lactation.
<i>Somatomammotropic effect</i>	The growth of breast function regulatory effect.

Prolactin (PRL), a somatolactotropic pituitary hormone of paramount importance in lactation, is under tonic inhibition primarily by the tubero-infundibular dopaminergic neurons (TIDA). Psychotropic medications (the class of butyrophenones, i.e., haloperidol) increase PRL levels, whereas dopamine agonists (e.g., apomorphine and bromocriptine) suppress PRL secretion. Recent advances in neurochemistry have made drugs available that have antipsychotic actions without altering PRL secretion (e.g., clozapine). Thyrotropin-releasing hormone (TRH) increases serum PRL levels by a direct effect on the anterior pituitary

gland, as do many of the antipsychotic drugs. The latter act as dopamine receptor antagonists at the pituitary prolactotropes, thereby blocking the normal inhibitory effect of endogenous dopamine on PRL secretion. Dopamine, a key PRL inhibitory factor, is released from the hypothalamus and transmitted to the anterior pituitary gland by way of the hypophyseal portal vessels. Opiates increase PRL levels by a central action that may involve dopamine neurons. Hyperprolactinemia linked to a microprolactinoma is clinically manifested by disturbed gonadal function, decreased libido, and various psychological disturbances (i.e., anxiety and depressive states) that can be ameliorated in part by the administration of dopamine agonists and/or serotonin antagonists. Such observations, as well as the phenomenon of pseudopregnancy, raise the possibility of PRL being involved in central nervous system (CNS) circuits beyond those involved in pregnancy and lactation.

Animal studies have indicated that PRL receptor-deficient mice have hyperprolactinemia, presumably due to the lack of feedback stimulation of TIDA neurons, and that the chronic elevation of PRL secretion occurs in rodents lacking a functional D₂ dopamine receptor. These findings suggest that PRL gains access to the CNS, presumably, via the arcuate-median eminence region, which has an incomplete blood–brain barrier. In experiments transplanting the pituitary to the kidney, there is excess PRL production because the pituitary grafts are remote from the site of dopamine release (in the hypothalamus).

The demonstration that there is PRL mRNA in the hypothalamus and other brain areas suggests that the behavioral effects assigned to PRL may relate to its presence in monoaminergic and peptidergic neurons. Immunohistochemical and *in situ* hybridization

studies revealed that PRL receptors are expressed in the arcuate, periventricular and medial preoptic nuclei both in male and nonpregnant female rats. In addition, during pregnancy and lactation PRL receptor immunoreactivity becomes demonstrable in the paraventricular nucleus (PVN) and ventromedial nucleus. The recruitment of a pleiad of neural structures during pregnancy and lactation assists in the provision of psychosomatic balance, needed for adequate nourishment of the mother and the fetus. The suppression of anxiety, reduced stress response, and expression of maternal behavior are linked to the activities of the PVN and medial preoptic nucleus, whereas the activation of the supraoptic ventromedial and arcuate nuclei are involved in regulating fuel and electrolyte balance.

During late pregnancy and lactation, the acute stress response is attenuated; it is hypothesized that this involves the PVN and the hypothalamic-pituitary-adrenal axis. The observation that PRL has dose-dependent anxiolytic effects in males and nonpregnant female rats (effects neutralized by the administration of antisense nucleotides against the PRL receptor), strongly suggests that PRL has a role as an endogenous anxiolytic. Stress-activated circuits enhance the release of cortical and medullary adrenal biological response modifiers – the glucocorticoids and catecholamines, respectively. When insulin-induced hypoglycemia (IIH) is used as a stressor, there may be an elevation of serum growth hormone (GH) and PRL. The blockade of PRL and enhancement of GH can be effected by dopamine agonists; an earlier clinical observation suggested that cyproheptadine blunts PRL release secondary to IIH, implicating indirectly the participation of serotonergic pathways. Whether the latter neurotransmitter is involved in the PRL release associated with the stress of anesthesia, sleep, nipple stimulation, gynecological exam, or exercise is unknown. Certainly, in contrast to dopamine and dopamine agonists, which block TRH-induced PRL release, serotonin (5-HT) antagonists are ineffective.

Beyond these observations about acute short-lived stress, there are some clinical observations that have stimulated research on psychological-psychiatric distress and PRL dynamics, independently of the activation of the hypothalamic-pituitary-adrenal axis. A woman on a birth-control pill in her teens developed breast engorgement and spontaneous bilateral galactorrhea, which reappeared 5 months later following general anesthesia for an orthopedic procedure. She had postpill amenorrhea with normoprolactinemia and no pituitary tumor; bromocriptine resulted in the cessation of galactorrhea and the reappearance of menses. This and other reports of dopamine agonist use in normoprolactinemic amenorrhea raise the

question: what is normoprolactinemia in aberrant psychological situations? In earlier observations, during acrobatic flight, we observed a significant rise in serum PRL only in novices and not in trained pilots. Transient PRL elevations have been reported during medical interviews, before medical and/or competitive examinations, during argumentative conflicts in neurotic women, and during panic attacks (in the last, it was mentioned that the PRL increase was more consistent than that observed for cortisol, GH, or catecholamines).

In a study carried out in epileptics with a non-lateralized focus following galvanic stimulation of implanted electrodes (in the amygdala and hippocampus), we observed different GH and PRL responses in the corticomedial and basolateral amygdaloid regions. These and other reports (i.e., the different profiles of serum PRL among patients with unipolar vs. bipolar disorders) point to the involvement not only of the infundibular but also of mesocortical and mesolimbic dopamine systems controlling surges, circadian, and sleep-related PRL regulatory circuits. It was recently reported that hyperprolactinemic amenorrheic women had significantly higher symptom questionnaire scores on hostility, anxiety and depression than normoprolactinemic amenorrheic women or women with normal menstrual cycles. Thirty of these women met the *Diagnostic and Statistical Manual of Mental Disorders* (3rd edn.; DSM-III) criteria for major depressive disorder, opening a PRL window for biological psychiatric research. An example along these lines is pseudopregnancy, which is considered a psychiatric condition in DSM-III (hysterical conversion neurosis); that is, the woman, firmly believing that she is pregnant, develops many of the symptoms and signs of pregnancy. In the absence of a prolactinoma, pseudopregnancy had been identified by Hippocrates: "If a woman is not pregnant and has not given birth, produces milk and her menstruation has stopped."

It is beyond any doubt that stress-induced hyper- or normoprolactinemic anovulation operates protectively for both the mother and the potential conceptus, for which the *milieu interieur* could be hostile. In the lactating, breast-feeding mother, the psychosomatic and immune well-being of the family (father, mother, and newborn) complex is preserved because breast-feeding inhibits ovulation and associated side effects. The immunoprotective actions of the somatolactotropic hormones and the maintenance of euthyroidism have been proposed as immunoprotective mechanisms ensuring reduced susceptibility to stress-induced disease. It is hoped that, in women with postpartum depression, hypnosis, psychotherapy, and the proper

choice of psychobiological response modifiers can be selected so that the hormonal-metabolic homeostasis is preserved.

Glossary

Adrenocorticotropin (ACTH)

A 39-amino-acid peptide released from the pituitary in response to stress that acts on the adrenal cortex promoting the synthesis and release of corticosteroids.

α-Melanocyte-stimulating hormone (α-MSH)

A peptide consisting of the first 13 residues of ACTH, produced mainly in the intermediate lobe of the pituitary. This peptide plays a role in the control of skin color in lower animals and in the control of feeding in mammals.

Immuno-precipitation

A purification process in which a specific antibody is used to capture a protein or peptide from a complex mixture (e.g., cell extract).

Prohormone convertases

A family of serine proteases that cleave proteins in the Golgi apparatus/secretory

	granule before they are secreted into the circulation.
<i>Pro-opiomelanocortin (POMC)</i>	A 30 kDa protein synthesized predominantly in the pituitary that is the common precursor to ACTH and several other biologically active peptides.
<i>SDS-PAGE</i>	(Sodium dodecyl sulfate polyacrylamide electrophoresis) A method to separate proteins by size using electrophoresis through a gel matrix.

Introduction

Adrenocorticotropin (ACTH), like the vast majority of peptide hormones, is synthesized as part of a large, biologically inactive precursor protein that is then proteolytically processed to release the active peptides. ACTH is derived from pro-opiomelanocortin (POMC), a 30-kDa protein that is the common precursor to a number of biologically distinct peptides, an N-terminal region (N-POMC 1–76), ACTH, and β -lipotropin (β -LPH). These peptides can be further cleaved to give β -endorphin, corticotropin-like intermediate peptide (CLIP), and N-POMC 1–49. POMC also contains three copies of the melanocyte-stimulating hormone (α -, β -, and γ -MSH) sequence. The name of the protein thus encompasses the names of the peptides it encodes.

Discovery of POMC

The concept of hormone precursors was developed in the 1960s when it was shown that insulin was synthesized as a larger molecule, pro-insulin, and was released by limited proteolysis. During the 1970s evidence accumulated that implied a very close link between ACTH and β -LPH. The two peptides were released in approximately equimolar amounts from the pituitary, while immunocytochemistry showed the two peptides colocalized in the same cells. This evidence suggested that the peptides were derived from the same precursor, and in 1977 this hypothesis was proved to be correct when two groups showed, in two entirely different ways, that indeed ACTH and β -LPH were derived from the same molecule. Mains and Eipper used a pulse chase approach with the mouse pituitary tumor cell line AtT-20, which secretes large amounts of ACTH. They incubated the cells with radiolabeled amino acids (the pulse) and then washed the radioactivity away after a short period (the chase), thus labeling all proteins synthesized during the period of the pulse. By taking the cells at different times after the chase and immunoprecipitating the cellular protein using either an ACTH or β -endorphin antisera followed by SDS-PAGE analysis,

they identified a common 31-kDa protein that became progressively smaller with time after the pulse until it became fully processed.

The second group, headed by Ed Herbert, also used the AtT-20 cell line together with a cell free translation system. Messenger RNA was purified from the cells and expressed in the cell free system. In this way a 28-kDa protein was identified that was recognized by both ACTH and β -endorphin antisera. The apparent difference in size was accounted for by the absence of glycosylation.

Although these experiments gave conclusive evidence that indeed ACTH and β -LPH were derived from the same protein, it was not until 1979, when the cDNA encoding POMC was cloned from both the bovine intermediate lobe and the mouse pituitary cell line AtT-20, that the true structural relationship between ACTH and β -LPH was revealed. Since then the POMC gene has been cloned and sequenced from a variety of organisms. In every species examined, it has been found that there is a single functional copy of the gene, and the overall gene structure, with the exception of the loss of γ -MSH in the salmon, has remained conserved throughout evolution. In the human it consists of three exons and two introns. Exons 2 and 3 are translated, with exon 2 coding for 44 amino acids; the remaining 223 residues are coded for by exon 3. The precursor molecule (pre-POMC) has a 26-amino-acid signal sequence followed by a 76-residue peptide (N-POMC or pro- γ -MSH) that contains one copy of the MSH sequence. This is followed by a joining peptide, ACTH, whose sequence encompasses the second MSH sequence (α -MSH), and finally β -LPH at the C-terminus, the sequence of which includes that for β -endorphin and the third MSH sequence. All the bioactive peptides within POMC are flanked by dibasic amino acid residues, e.g., Arg-Lys, Arg-Arg, Lys-Arg, and Lys-Lys. The structure of POMC and the major peptides released as a result of proteolytic cleavage are shown in [Figure 1](#).

Sites and Tissue-Specific Processing of POMC

The main site of POMC expression is the anterior and intermediate lobes of the pituitary. In the anterior lobe, POMC represents approximately 1% of total protein, while it represents up to 10% in the intermediate lobe. Although these two tissues make up the principle sources of circulating POMC, it is also expressed and processed in several other tissues throughout the body, including the adrenal, gut, reproductive tract, placenta, leukocytes, spleen, lung, liver, thyroid, heart, skin, and brain.

Figure 1 Structure of the POMC gene and the protein it encodes. Positions of the dibasic residues and the Cys residues are shown. Regions of the precursor conserved between species are also shown.

One advantage of producing peptides from a larger precursor is that the precursor can be cleaved in a tissue-specific manner to give a different set of products depending on tissue that the precursor is synthesized in. POMC is the classical example of this so-called tissue-specific processing, with the major sites of synthesis being the anterior and intermediate lobes of the pituitary. Classically, the pituitary can be divided into three distinct tissues:

1. The anterior pituitary or pars anterior contains a mixed population of cells, some of which, named corticotrophs, secrete POMC peptides that are involved mainly in the control of adrenal function.
2. The intermediate lobe or pars intermedia consists solely of melanotrophs that secrete POMC-derived peptides that are involved mainly with skin and hair pigmentation.
3. The posterior pituitary or pars nervosa stores and releases vasopressin and oxytocin produced in the hypothalamus.

In the rat these three tissues can be clearly defined, but in adult humans there is no distinct pars intermedia. It is present in fetal life but disappears soon after birth, leaving just a few scattered cells throughout the anterior lobe, giving the adult anterior lobe the collective name of pars distalis. The region between the anterior and posterior lobes is sometimes called the zona intermedia.

Processing of POMC in the Anterior Pituitary

Processing of the POMC in the anterior pituitary is summarized in [Figure 2](#). The mouse anterior pituitary cell line AtT-20 has been used extensively as an *in vitro* model for processing in the anterior lobe. Using pulse chase experiments it was determined that the major products were a 16-kDa N-terminal fragment, ACTH, and β-LPH. β-endorphin can also be formed from sequential cleavage from β-LPH (not from direct cleavage of POMC) but is only a minor product.

Processing of POMC in the Pars Intermedia

Within the pars intermedia, processing is more extensive, with the sequential cleavage of peptides produced in the anterior lobe. ACTH is cleaved to α-MSH and CLIP, while β-LPH is virtually completely processed to β-endorphin, and γ-LPH. β-endorphin (1-31) is cleaved at the C-terminus to give β-endorphin(1-27), β-endorphin(1-26), and a dipeptide glycylglutamine. The majority of the β-endorphin is N-acetylated. The N-terminal fragment N-POMC 1-76 is partially cleaved at an Arg-Lys site to give N-POMC 1-49 and Lys-γ3-MSH. This latter peptide contains an additional dibasic site (although not in all species) but does not appear to be cleaved to any significant extent.

Figure 2 Processing of POMC in anterior and intermediate lobes of the pituitary. Dibasic cleavage sites are shown as vertical lines. Dashed arrow indicates incomplete processing.

Molecular Basis of Tissue-Specific Processing

POMC is itself biologically inactive and must be processed correctly to its biologically active peptides. During and after sorting and packaging of the POMC precursor into the regulated secretory vesicles, and prior to the release of the nascent secretory vesicles from the trans Golgi network, it is endoproteolytically cleaved. Cleavage is normally elicited at dibasic amino acid residues and follows a common route involving three different enzymes:

1. An endoprotease that cleaves on the C-terminal side of the basic amino acid pair.
2. A carboxypeptidase-B-like activity that removes the basic amino acid left after cleavage. Carboxypeptidase E (CPE) (also called CPH) specifically removes the basic residues from the C-terminus of a peptide.

3. A C-terminal amidating enzyme that catalyses the amidation of peptides terminating in glycine. The enzyme peptidylglycine alpha-amidating monooxygenase (PAM) catalyses this reaction and utilizes a glycine situated on the N-terminal side of the dibasic cleavage site as the nitrogen donor for the amide group.

These processing events are carried out in an acidic environment within the trans Golgi network or within the immature secretory vesicles and are necessary for the optimum activity of the processing enzymes as well as to induce conformational changes in the protein to expose the basic amino acid residues for cleavage.

In most cases, specific processing of prohormones occurs on the carboxyl side of pairs of basic amino acids, usually Lys-Arg or Arg-Arg sites. Processing

can also occur at the tetrabasic sequence Arg-X-Lys/Arg-Arg and less frequently at monobasic sites. The enzymes that have implicated in the specific processing of POMC are known as prohormone convertases 1 and 2 (PC1 and PC2). These two enzymes are members of the subtilisin family of Ca^{2+} -dependent serine proteinases.

Identification of the Enzymes Involved in POMC Processing

During the early 1990s the identification of the prohormone converting enzymes was a major aim of researchers in the field. The breakthrough came with the cloning of a yeast gene called KEX2. The product of the KEX2 gene, known as kexin, is a protease that cleaves the yeast alpha factor mating pheromone. Cellular expression of the gene demonstrated that the enzyme belongs to the subtilisin family of Ca^{2+} -dependent serine proteinases. KEX2 has the ability to selectively cleave a number of mammalian prohormones, and this led to the hypothesis that similar mammalian counterparts existed.

The first mammalian gene to be identified as a potential processing enzyme came as a consequence of computer alignment of the amino acid sequences surrounding the serine and catalytically important asparagine of kexin against known protein sequences. By this method, a human gene of unknown function was identified, named *fur*, which lies upstream from the

tyrosine kinase *fps/fes* proto-oncogene. The product of this gene, to become known as furin, was to become the first mammalian processing enzyme identified.

Using the sequence of the two eukaryotic proteases and several other subtilisin sequences, Smeekens and Steiner designed degenerate oligonucleotides corresponding to the conserved active site. By utilizing these in the polymerase chain reaction (PCR) with cDNA isolated from a human insulinoma library as template, they generated a fragment that was then used to probe that library. A full-length cDNA was identified that encoded for a protease that became known as PC2. Concurrently, Seidah and colleagues, using a similar procedure with the sequence of furin and a mouse pituitary library, identified two cDNA clones that were to become known as PC2 and PC1.

Elegant studies performed *in vitro* using cell-based assays and recombinant enzymes, together with studies looking at PC1 and PC2 knockout animals, have revealed the molecular basis of the tissue-specific processing observed in the anterior and intermediate lobes. In the anterior lobe, PC1 is the predominant enzyme present, and due to its more limited proteolytic activity, results in the generation of ACTH. However, in the intermediate lobe, both PC1 and PC2 are present, and their coordinate actions result in the generation of the smaller POMC peptides.

Cleavage of POMC occurs in a specific order and is summarized in [Figure 3](#).

Figure 3 Processing of POMC by PC1 and PC2. The order of cleavage is dictated by the numbers showing that PC2 acts on the products of PC1 cleavage.

Regulation of the Expression of the POMC Peptides

As the processing of POMC occurs in a tissue-specific manner, it follows that the control of POMC expression and secretion of the derived products are also tissue specific.

Anterior Pituitary

With POMC produced in the pituitary, it followed logically that its secretion was under the control of factors released from the hypothalamus. In 1981 Vale identified the first of these as a 41-amino-acid peptide called corticotropin-releasing hormone (CRH). However, CRH does not stimulate ACTH release to the same extent as hypothalamic extracts, and it became clear that at least one other substance stimulated the release of ACTH. This second substance was identified by Lowry, McCann, Antoni and other investigators as arginine vasopressin, which potentiates the ACTH-releasing activity of CRH. Stimulation by CRH results in an increase in POMC mRNA levels as well as an increase in secretion of peptides. The two main factors are also potentiated by the action of several other weak secretagogues, namely, epinephrine, norepinephrine, oxytocin, and angiotensin II.

Observations after treatment with exogenous glucocorticoids or adrenalectomy have long implicated a role for glucocorticoids in the control of POMC peptide secretion. They exert their effects both at the hypothalamus, by decreasing CRH secretion, and at the corticotroph, by decreasing POMC synthesis.

Pars Intermedia

As would be expected, the regulation of POMC expression and secretion in the pars intermedia is quite distinct from that in the pars anterior. Glucocorticoids have no influence on POMC expression; although receptors are present, they do not seem to elicit any control over POMC gene expression.

POMC gene expression is enhanced by stress CRH and β -adrenergic agonists. All exert their actions via cAMP.

Dopamine decreases POMC expression by binding to D2 receptors, which are thought to block the activation of adenylate cyclase, although there may be more direct effects.

Posttranslational Modifications of POMC

POMC and its peptides undergo a number of different modifications following POMC's synthesis and removal of the signal peptide.

Disulfide Bridge Formation

Human POMC contains five Cys residues, one more than every other species. Four occur close to the

N-terminal at positions 2, 8, 20, and 24, while the fifth occurs in the joining peptide. The four N-terminal Cys residues form intramolecular disulfide bridges between 4 and 24 and 8 and 20. The fifth Cys, contained within the joining peptide and unique to humans, leads to its secretion as a homodimer, which may indicate that human POMC is produced as a dimer.

Glycosylation

In all species Asn 65 is N-linked glycosylated in the consensus sequence Asn-X-Ser. O-linked glycosylation also occurs at Thr 45 in the human and porcine pituitary.

Phosphorylation

Serine 31 of ACTH is phosphorylated in the rat, human, and mouse, although its presence has no effect on biological activity.

Acetylation

α -MSH and β -endorphin are found as des-, mono- and diacetylated forms, although the precise form varies between tissue and species. The N-terminal Ser of α -MSH may be acetylated through either the hydroxyl or amide group, acetylation increasing both its biological activity and half life, in contrast to β -endorphin, which reduces its biological opiate activity.

Biological Activity of the POMC Peptides

The peptides contained within the POMC precursor have a wide spectrum of biological activity that is briefly described in the following sections.

Adrenocorticotropin (ACTH)

The main role of ACTH is to promote steroidogenesis within the adrenal cortex. It exerts its actions by binding to the melanocortin 2 receptor (MC2R), leading to a rise in the levels of cAMP and activation of protein kinase A, resulting in secretion of glucocorticoids, androgenic steroids, and, to a lesser extent, mineralocorticoids. The acute effect of ACTH is to increase the rate of conversion of cholesterol to pregnenolone, the first and rate-limiting step in the steroidogenic pathway. The chronic effects of ACTH result in an upregulation of the expression of most of the enzymes involved in the steroidogenic pathway.

ACTH has also been implicated in the maintenance of adrenal weight. The evidence for this is based heavily on the observation that long-term glucocorticoid therapy results in adrenal atrophy. However, since all POMC peptides are downregulated during such treatment and administration of ACTH alone

does not totally reverse the atrophy, it is clear that other POMC peptides play a role in the control of adrenal weight.

N-Terminal Peptides and Adrenal Growth

The role of the N-terminus of POMC in adrenal growth was originally proposed in the early 1980s, when a series of elegant studies demonstrated that N-terminal peptides could stimulate mitogenesis in adrenal cell cultures. It was also shown that immunoneutralization of N-POMC peptides resulted in the inhibition of the compensatory growth response observed following unilateral adrenalectomy.

However, N-POMC 1–76 is itself inactive, but peptides derived from its N-terminus, not containing γ -MSH, are potent adrenal mitogens. Since these shorter peptides are not generated during normal pituitary processing, it was proposed that N-POMC 1–76 is cleaved after secretion. Considerable weight has recently been added to this argument with the identification of an adrenal protease that appears to cleave N-POMC to the shorter forms.

Melanocyte-Stimulating Hormone

There are three copies of the MSH sequence in the POMC precursor: α -MSH in ACTH, β -MSH in β -LPH, and γ -MSH in N-POMC 1–76. The biological role of the MSH peptides in lower vertebrates such as frogs was known before the discovery of POMC. α -MSH produced by the pars intermedia causes the darkening of skin to match a darker background. Both α -MSH and β -MSH share the common core sequence Met-Glu-His-Phe-Arg-Trp-Gly, which is essential for biological activity. γ -MSH contains the sequence Met-Gly-His-Phe-Arg-Trp-Asp and was named due to its similarity to the other MSH sequences. However, it has no melanotropic activity.

The role of the MSH peptides in skin pigmentation in humans is not clear. Injection of the peptides into humans does result in skin darkening. Also, in Nelson's syndrome, a condition in which there are high levels of POMC peptides, skin darkening is observed. However, in the normal human this role is debatable. Humans do not have any pars intermedia tissue, and certainly there are no detectable amounts of α -MSH in the periphery, although mRNA encoding POMC can be detected in human skin.

Role of MSH Peptides in the Regulation of Feeding

Mammals regulate their energy stores relatively constantly despite a large variation in both food availability and physical activity. The control of energy

expenditure has been shown to be the result of a complicated endocrine loop involving a number of neuropeptides, including the melanocortins.

POMC is synthesized in the hypothalamic arcuate nucleus, where it is processed in a manner similar to that observed in the intermediate lobe. It has been generally assumed that α -MSH is the most important peptide since it is the ligand with highest affinity for the two melanocortin receptors – the MC3R and MC4R expressed in the hypothalamus. Genetic and pharmacological disruption of this loop causes obesity in both humans and rodents. The POMC knockout mouse is hyperphagic and obese, whereas infusion of α -MSH (or synthetic agonists) results in anorexia and weight loss.

The complete subtle architecture of this system is still far from clear, but the system's potential as a therapeutic target for the treatment of obesity has made it the focus of intense research over the past few years.

γ -MSH and Steroidogenesis

γ -MSH is generated from N-POMC in the intermediate lobe of the pituitary. It contains a slightly modified core sequence, Met-Gly-His-Phe-Arg-Trp-Asp, and has a biological role distinct from that of α -MSH.

Studies performed by Alastair Brownie in the early 1980s identified γ -MSH as a regulator of hormone sensitive lipase (HSL). This enzyme is found in steroidogenic tissues and breaks down cholesterol esters to free cholesterol, which then feeds into the steroidogenic pathway. Several groups demonstrated that although not directly steroidogenic, this peptide can synergize with ACTH and result in an increase in steroid output. The receptor through which this peptide acts is unclear, since although the MC3R has been shown to be the only melanocortin receptor with significant affinity for γ -MSH, its expression profile and pharmacology suggest that it does not play a role in this system.

Joining Peptide

The joining peptide has no known biological function. Its role, like the C-peptide of insulin, is probably only to provide a spacer between the different peptides. One interesting feature of human joining peptide is that it uniquely contains a cysteine that has been implicated in dimer formation.

β -Endorphin

β -endorphin is one of several endogenous opioids that exert their actions by binding to receptors within the central and peripheral nervous systems. It is part of a larger family whose members include dynorphin and

the enkephalins. The opioids bind to three receptors known as the μ , κ , and δ opioid receptors. The receptors derive their names from the opiate agonists that bind to them: morphine and ketocyclazocine for the μ and κ receptors, and the vas deferens for the δ receptor, where it is located. The receptors differ in their affinity for the different opioids, although not one is specific for a single ligand. β -endorphin and Met-enkephalin bind to the μ and δ receptors, while dynorphin binds to the κ receptor. All the receptors are G-coupled and recognize a common motif consisting of a protonated amine adjacent to an aromatic amine, for example, the tyrosine residue at the N-terminus of the enkephalins. The opioid actions of β -endorphin are dependent on its C-terminal residues. Removal leads to a decrease in both its analgesic properties and binding affinity for the receptors. Thus, the shorter endorphins lack opioid activity, as does N-acetylation of the peptide. The N-terminal portion of β -endorphin is required for binding to the opiate receptors, whereas the C-terminal residues are thought to enhance the binding affinity.

Conclusions

Most peptide hormones are produced as inactive precursor molecules that are subsequently cleaved at dibasic residues to release the active peptides. As the first such multihormone to be discovered, over a

quarter of a century ago, POMC has been extensively studied and characterized. Its role in the control of adrenal function by the actions of ACTH on steroidogenesis, as well as N-POMC on the control of adrenal tonic state, are central to the stress axis as a whole.

Introduction

Characteristics of Prostaglandins

Prostaglandins in the Hypothalamic-Pituitary-Adrenal Axis

Stress and Antistress: Prostaglandins versus Glucocorticosteroids

Glossary

Adrenals

The organs that cap the kidneys. The outer layer, the cortex, synthesizes the corticosteroids, whereas the inner layer, the medulla, synthesizes epinephrine.

Cytokines

Regulatory proteins, such as the interleukins and lymphokines, that are released by cells of the immune system and act as intercellular mediators in the generation of an immune response.

Glucocorticosteroids

Anti-inflammatory steroids; also called glucocorticoids. Cortisol and corticosterone are natural corticosteroids secreted by the adrenal cortex and have strong glucocorticoid activity.

Hypothalamus

A specialized area in the brain that regulates automatic body functions such as temperature, sleep, and water balance. It coordinates the endocrine system.

<i>Noradrenergic cells</i>	Nerve cells that release norepinephrine.
<i>Nonsteroidal anti-inflammatory drugs (NSAIDs)</i>	Drugs (e.g. aspirin, indomethacin) that act by inhibition of the cyclo-oxygenases (COX-1 and COX-2) and hence prevent prostaglandin synthesis.
<i>Phospholipids</i>	Lipid (fat) molecules with a nonlipid phosphate head. Phospholipid bilayers are the basic components of cell membranes.
<i>Phosphorylation</i>	The process of adding phosphorus to a dormant enzyme, thereby activating it. Occasionally, phosphorylation deactivates an active enzyme.
<i>Pituitary</i>	The master endocrine gland that lies just beneath and is attached by the pituitary stalk to hypothalamus. The pituitary controls major endocrine systems, growth, body water and electrolytes, lactation and parturition. The pituitary gland is under central nervous control, which in the case of the anterior pituitary gland is mediated by hypothalamic neurohormones transported from the hypothalamus by the hypophyseal portal vessel system.
<i>Prostaglandins (PGs)</i>	A family of hormones whose chemical structure is identical, except for small changes in the pentane ring; these differences provide the distinguishing nomenclature (prostaglandin D, E, F, and I and thromboxane A). The subscript in the name (e.g., PGD ₂) refers to the number of unsaturated carbon bonds.
<i>Stressors</i>	Any agent that induces stress in the intact animal or in cell or tissues in culture.

Introduction

Stress, generally classified in terms of emotional or physical, presents a very clear pattern of pathophysiological changes. These are the consequences of stimulation by the many biologically active agents – hormones, neurotransmitters, and cytokines – generated by the nervous, endocrine, and immune systems aroused by stress. To a large extent, the systems are interdependent, and their complex networking is still far from being completely understood. The body maintains its healthy state by continuously readjusting to the changing environment, a process known as homeostasis. Stressors push the homeostatic mechanisms beyond normal limits, and the body enters a new, temporary state called stress.

The participation of the main agents of stress, adrenocorticotrophic hormone (ACTH), corticosteroids, and catecholamines (CAs), has been long established. PGs, which are local rather than transported hormones, are not among these main stress hormones

Table 1 Stages in the response to a stress signal that may be affected by prostaglandins

<i>Stages of stress response</i>	<i>Prostaglandin link</i>
Recognition of stress signal	Unclear
Initiation of stress response	Positive
Transmission and modulation of stress response	Possible
Expression of stress symptoms	Positive

that are poured out immediately in response to stress. However, cells from stressed animals produce more PGs than controls do, and PG levels in serum, spinal fluid, and the hypothalamus are elevated during stress. The role of PGs in stress is still largely undefined, but they appear to be involved in at least two stages (Table 1): (1) the initiation of the stress response in the brain and (2) the expression of some symptoms of stress.

Characteristics of Prostaglandins

Background

As first reported in the 1930s, PGs were the most powerful, ubiquitous, diversified, and mysterious biological substances yet discovered. Some 30 years later, they were finally unmasked by the Swedish medicinal chemists Sune Bergström and Bengt Samuelsson, who in 1982 were awarded the Nobel Prize in Physiology with the British pharmacologist John Vane. They isolated, identified, and characterized the PG family, establishing unsaturated lipids derived from the cell membrane as an unexpected class of highly sensitive bioactive regulators. Thanks to Vane and colleagues, the mechanism of action of aspirin, the first of the manufactured NSAIDs and one of the most successful drugs ever to be marketed, was now, some 70 years later, finally elucidated, proving to be a specific inhibitor of PG synthesis.

Synthesis of Prostaglandins

Cell membranes, comprising largely phospholipids, are themselves the major source material for PGs and other biologically reactive eicosanoids (20-carbon unsaturated carboxylic acids) such as leukotrienes (LTs).

Phospholipase A₂ Arachidonic acid (AA), an unsaturated fatty acid, is detached from membrane phospholipids by the enzyme phospholipase A₂ (PLA₂), transformed by cyclo-oxygenases (COXs) into the unstable endoperoxide PGH₂, and then metabolized by the various synthases to PGE₂, PGF_{2α}, PGD₂, prostacyclin (PGI₂), or TXA₂ (Figure 1). The superfamily of the PLA₂ enzymes consists of 14 groups (I–XIV)

Figure 1 Prostaglandins and their synthesis. COX, cyclo-oxygenase; LOX, lipoxygenase; LT, leukotriene; PG, prostaglandin; PGI₂, prostacyclin; PLA₂, phospholipase A₂; TXA₂, thromboxane A₂.

and at least 19 members. The low-molecular-mass (~12- to 19-kDa) secretory PLA₂ (sPLA₂) proteins are all related evolutionarily, share a common catalytic histidine, and fall into the groups I–III, V, and IX–XIV. A high-molecular-mass (60- to 110-kDa) family of calcium-dependent (requiring micromoles of Ca²⁺ for activation) cytosolic PLA₂ (cPLA₂) proteins use a catalytic serine and have a high specificity to AA. Some are activated by Ser505 phosphorylation, use a novel catalytic dyad of Ser228 and Asp549, and are designated group IV (A, B, C or α , β , γ cPLA₂). The calcium-independent PLA₂ (iPLA₂) (group VI) contains eight ankyrin repeats, has a lipase consensus sequence with an active serine that serves as a nucleophile, plays a role in phospholipids' remodeling and homeostasis via the production of lysophospholipids, and falls into the subgroups (A-1, A-2, and B). Groups VII and VIII PLA₂ are platelet-activating factor (PAF)-acetylhydrolases that cleave PAF to form lyso-PAF and a free acetyl group. mRNA expression of cPLA₂ is enhanced by pro-inflammatory cytokines and inhibited by glucocorticoids (GCs).

An alternative and equally important route for AA is metabolism by lipoxygenases (LOXs) to the exceedingly potent LT derivatives (Figure 1). Like PGE₂ and PGF_{2 α} , LTs mediate inflammatory and allergic reactions, but their contribution to stress is largely uncharted. Other branches of the PG–LT

family are also not discussed in this article; they appear to be less bioreactive and less is known in general about their contribution to pathophysiological mechanisms.

Cyclo-oxygenases The COX enzyme was first known as PGH₂ synthase (PGHS) because of its ability to catalyze the first two reactions in PG synthesis from arachidonate to PGH₂. COX was first isolated in 1976, and its two isoforms, COX-1 and COX-2, were discovered around 1992. The two isoforms (71 kDa), are encoded by different genes, are structurally similar, are composed of some 600 amino acids, and catalyze the same substrate. The enzymes contain a heme group that binds molecular oxygen. COX-1 is mainly found in the endoplasmic membrane, whereas COX-2 is found also in the nuclear envelope. The active sites of the two enzymes differ, which may explain why the enzymes are inhibited by different drugs. COX-1 is constitutive (i.e., always present in almost all cell types) and is associated with normal physiological PG activities, such as protection of the kidney and the stomach lining from damage and maintenance of vascular homeostasis. However, COX-2 is induced by stimuli, both stressful ones such as inflammatory agents and natural ones such as growth factors; it is also found constitutively in a few organs, one of which is the brain. It is not, however, expressed in nerve cells that synthesize the PGs responsible for stress-induced fever, hyperalgesia, and sleepiness. The origin of this stress-induced COX-2 is the endothelial cells lining the blood vessels in the brain, which are accessed easily by the PG-stimulating blood-borne cytokines. Anti-inflammatory GCs, complexed with their specific receptors, penetrate the nucleus, bind to DNA at the hormone response element sequence, regulate transcription, and preferentially suppress the induction of COX-2.

Nature and Functions of Prostaglandins

Prostaglandins are very potent local hormones that are synthesized rapidly by a wide variety of cells in the body. PGs are released into the extracellular space by specific PG transporters. Once released, PGs bind to their cognate receptors, which belong to the G-protein-coupled receptor (GPCR) superfamily. There are four major receptor subtypes for PGE₂ (EP1, EP2, EP3, and EP4), which are encoded by separate genes. There is a major receptor for PGF_{2 α} (FP), for PGD₂ (DP), and for PGI₂ (IP). The various PG receptors differ in their signaling pathways. Sequence homology is found between receptors that share a signaling cascade rather than a ligand. Therefore, the group IP, DP, EP2, and EP4, which act via Gs to elevate cAMP levels, are known as the relaxant receptors because of

their common effect on smooth muscle relaxation. The contractile receptors TP, FP, and EP1 mobilize calcium via Gq and induce smooth muscle contraction. PGs, therefore, act in an autocrine/paracrine manner via cognate GPCRs. Within a short time, usually less than 30 min and in the case of thromboxane A₂ (TXA₂) a mere 30 s, PGs are inactivated (90%) to oxidized metabolites when passing through the lungs; very little PG is normally found in the circulation.

Pathological functions of prostaglandins and connections with stress PGs almost always act in the vicinity of their synthesis. The blood-borne, pro-inflammatory cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- α are released from leukocytes in the blood and macrophages in tissues and are among the agents that locally trigger PG synthesis.

- **Inflammation.** Traumatic, inflammatory, immune, or other foreign stimuli trigger the activation and recruitment of PGs and LTs. They are part of the inflammatory reaction, promoting leukocyte infiltration, edema, and local vasodilation. Stress generates the same arachidonic AA metabolites and cytokines as inflammation.

- **Fever.** The elevation of body temperature, but not the maintenance of core temperature, is controlled by PGE₂ in the preoptic area of the hypothalamus. Stress-induced fever is reduced by the prior administration of aspirin-like drugs, such as indomethacin. The stimulation of PGE₂ synthesis in the endothelial cells of hypothalamic blood vessels by stressors such as lipopolysaccharide (LPS), which mimic the symptoms and the stress of bacterial infection in experimental animals, elevates body temperature. Fever also accompanies the stress of surgery (trauma), pain, and cage switching in rats, restraint in pigs, and open field (but not the stress of restraint) in rats or pigs being transported or frustrated by a lack of reward after exhibiting reward-training behavior.

- **Hyperalgesia.** Heightened sensitivity to pain, or hyperalgesia, is another stress symptom related to PGs. Pain is processed along the spinothalamic tract, reaching the thalamus, limbic system, and frontal cortex before descending through moderating pain-inhibitory nerve pathways. Stress-induced COX-2 is most evident in the spinal cord. Animal models of inflammatory stress and pain, such as carrageenin injected into rat foot pads, show that PGs are generated locally at the sensory nerve endings and in the spinal cord and cause hyperalgesia. COX-2 inhibitors (such as NS398 and DuP 697) and mixed COX-1 and

COX-2 inhibitors (such as aspirin and indomethacin), applied directly to the spinal fluid, are analgesic.

- **Dysmenorrhea.** Dysmenorrhea is a condition with painful menstrual periods with uterine hypercontractility. Increased levels of PGE₂ and PGF_{2 α} were found in the menstrual fluid of women with dysmenorrhea, and COX enzyme inhibitors alleviate the pain.

- **Endometriosis.** Endometriosis occurs when endometrial tissue is found in extrauterine sites; it is associated with pelvic pain and infertility. The increased production of PGE₂ and PGF_{2 α} and overexpression of COX-2 are thought to be associated with endometriosis. Estrogen and angiogenic factors, such as vascular endothelial growth factor (VEGF), may be involved in the proliferative responses induced by the PGs in endometriosis.

- **Cancer.** Various studies have indicated a role for the COX enzymes, PGs, and PG receptors in the pathology of cancers. The overexpression of the COX enzymes and PG receptors and the increased production of PG were found in various cancers. The studies suggested the use of COX enzyme inhibitors in treating some cancers. Because COX-1 is regarded as a constitutive enzyme, whereas COX-2 is the regulated enzyme, attention has been paid to the development of selective COX-2 inhibitors.

Some physiological functions of prostaglandins with connections to stress The various PGs have diverse and frequently opposing actions (Table 2). PGs used in nonpathological functions are synthesized mainly by the constitutive (maintenance) enzyme COX-1.

- **Blood pressure.** PGE₂ and prostacyclin (PGI₂) are vasodilators and have a role in normal blood pressure control. However, TXA₂ is a strong vasoconstrictor. Blood pressure rises in stress and is not affected by PG inhibitors.

- **Gastric ulcers.** In the gastrointestinal system, PGE₂ and PGI₂ protect the stomach lining by inhibiting gastric acid secretion and promoting the healing of ulcers. Prolonged use of aspirin or other NSAIDs to inhibit PG synthesis. Gastric ulcers are enhanced.

- **Preterm birth.** The presence of PGE₂ and PGF_{2 α} , both of which contract the pregnant uterus and are produced by uterine and fetal tissue, is essential for the survival of the fetus. During maternal or fetal stress, these PGs are induced and can lead to preterm birth.

- **Sleep.** A central function of PGD₂ is thought to be sleep induction. Its metabolic enzyme PGD₂ synthase is located in the cerebrospinal fluid and the meninges and choroid plexus, nonneuronal cells lining the whole central nervous system (CNS).

Table 2 Diversity of physiological and pathological effects of the prostaglandins^a

	<i>PGD₂</i>	<i>PGE₂</i>	<i>PGF_{2α}</i>	<i>PGI₂</i>	<i>TXA₂</i>
Blood pressure	Down	Down	No change	Down	Up
Airway	Constrict	Dilate	Constrict	Dilate	Constrict
Uterus (nonpregnant)		Relax	Contract		
Uterus (pregnant)		Contract	Contract		
Kidney (GFR)	Increase	No change		No change	Reduce
Stomach secretions		Inhibit	Stimulate	Inhibit	
Gut motility		Increase	Increase	Increase	Increase
Platelet aggregation			Inhibit		Stimulate
Sleep	Induce				
Fever		Induce			
Pain		Lowers threshold		Lowers threshold	

^aChart is not comprehensive.

Sleepiness is a stress response, and *PGD₂* could be involved in this process.

Stimulation of Prostaglandin Synthesis in Stress

Most stressors stimulate PG synthesis. Increased plasma (or medium) *PGE₂* was induced by heat, pain, trauma (bone fracture), exercise, LPS, restraint, water immersion, and cage switching. A fall in *PGE₂*, however, was associated with cold stress in rats and captivity in frogs. In these captive frogs, *PGF_{2α}* increased, as it also did in individuals subjected to the stress of surgery, students taking examinations, and cells that were heat-stressed. *PGI₂* was also increased by examination and surgery stresses, and it was removed from the aorta of immobilized rats.

In the brain of stressed animals, IL-1-stimulated *PGE₂* releases the corticotropin releasing hormone (CRH) in the hypothalamus, thus activating the hypothalamic-pituitary-adrenal (HPA) axis. Most studies report that *PGE₂* is synthesized by the cytokines in the brain; *PGF_{2α}* and *PGD₂* are also mentioned in such studies. PGs induced by IL-1, IL-6, and TNF- α in the preoptic area also bring about fever and cause hyperalgesia via the spinal cord (and at sensory nerve endings), whereas *PGD₂* in the cerebrospinal fluid and meninges induces sleep. The sources of these PGs are not necessarily neuronal but, rather, originate from the blood vessels, microglia, or other cells lining the brain.

Assay for Prostaglandins in Stress

Types of stress and measurement of prostaglandins

For pharmacological purposes, there is no gross difference between emotional and physical stress. Cell systems galvanized by the body to express and to cope with the stress of, for example, bereavement (emotional or psychological) are ultimately the same ones used in the stress caused by an illness (internal physical) or a supreme athletic effort (external

physical). An element of psychological stress generally accompanies a physical stress.

Experimental models of stress have been devised to mimic human stress-provoking situations, in which animals, or cells or tissues in culture, are subjected to one of a number of unpleasant procedures. In these models, stress behavior, in the presence and in the absence of drugs that modify PG synthesis, is observed and the biochemical changes are monitored. Alternatively, tissue samples are assayed for PGs, *PLA₂*, or COX-2 before and after provoking stress. PGs are commonly assayed using radioimmunoassay techniques, and enzymes are assayed by measuring their activity on labeled substrates or measuring their mRNA levels. Increases in enzyme activity (*PLA₂* and COX) and a rise in concentration of a specific PG have been consistently reported in many different stress states.

Inhibitors of prostaglandins Prostaglandin synthesis is inhibited by two groups of anti-inflammatory agents: NSAIDs and GCs (the very same hormones elicited by stress). NSAIDs interfere only with COX activity; the prime example is aspirin, although indomethacin is routinely used in experimental systems. These drugs inhibit COX-1 and COX-2 to varying degrees. COX-2-selective inhibitors (COXibs) such as Celecoxib (Celebrex) and Rofecoxib (Vioxx), developed in the 1990s, are relatively large inhibitors that penetrate the active site of COX-2 but not that of COX-1. They offered much promise when they first appeared on the market, but were found to be associated with a potential risk of myocardial infarction and sudden cardiac death. More recently, attention has been given to the pharmacology of the PG receptors. Efforts are being made to develop receptor-specific antagonists that will inhibit the biological action of the PG rather than their synthesis. GCs, such as dexamethasone, depress the whole AA metabolite network by partial inhibition of *PLA₂*

synthesis and control stress-induced PGs, in particular by preventing cells from inducing COX-2. The very strong anti-inflammatory action of GCs is due to their wide-ranging anti-inflammatory base. The GC receptor complex interacts directly with and regulates the gene transcription of many inflammatory enzymes and proteins, including COX-2. Inhibitors of PG have been widely employed in the stress models to determine the contribution of PGs to the stress symptoms. This use of PG inhibitors as indirect proof has its limitations because the NSAIDs that can distinguish between the various PGs have not yet been developed and GCs suppress a whole spectrum of agents provoked by stress.

Prostaglandins in the Hypothalamic-Pituitary-Adrenal Axis

Stress Hormone Flow

The perception of distress is instantly transmitted via one or more neural circuits, each with its own neurotransmitter system, to the median eminence (ME) in the hypothalamus. The production of CRH, the major stress hormone released by the hypothalamus, and arginine vasopressin (AVP) is intensified immediately and stimulates the anterior pituitary to release ACTH into the circulation. The adrenal cortex is stimulated by ACTH to produce cortisol and corticosterone, powerful GCs that, by suppressing the production of pro-stress agents, including PGs, keep the sharp stress response from running fatally out of control (Figure 2).

The sympathetic nervous system, also activated in stress, releases CAs into the circulation – norepinephrine (NE) and epinephrine (EPI) – setting the body in the stress-alert mode for flight or fight. CAs stimulate PG synthesis in many tissues, including the brain.

Prostaglandins in the Initiation of Stress Response

Prostaglandin activity has been located in the HPA axis, prior to CRH release. The stress-related PG presence has not been confirmed at other points along the axis. One of the CRH-stimulating neural circuits is noradrenergic. These neurons originate in and/or project to the paraventricular nucleus (PVN) of the hypothalamus and are stimulated by IL-1- and IL-6-induced PGE₂. The rat hypothalamus can synthesize PGE₂, PGF_{2α}, PGI₂, and TXA₂, but, at least *in vitro*, only PGE₂ is produced in response to IL-1 and IL-6, although PGD₂, PGF_{2α}, and TXA₂ also induce CRH release. The noradrenergic circuit that stimulates the HPA axis can stimulate PG synthesis and is inhibited by indomethacin. PGs also seem to be able to directly induce CRH or AVP release. Thus,

Figure 2 Activation of the hypothalamic-pituitary-adrenal (HPA) axis by stress. Release of adrenocorticotrophic hormone (ACTH) is under the negative control (–) of the corticosteroids it induces. Prostaglandin E₂ (PGE₂) stimulates the release of corticotropin releasing hormone (CRH) or arginine vasopressin (AVP) from the hypothalamus and mediates the noradrenergic activation of the HPA axis.

PGs may activate the HPA axis through the direct stimulation of CRH or AVP neurons or via noradrenergic neurons in the PVN (Figure 3).

Stress and Antistress: Prostaglandins versus Glucocorticosteroids

The stress-induced production of pathological PGs, together with anti-stress GCs, raises the question of their mutual operation during stress. The GC surge elicited by stress effects an inbuilt antistress facet to limit some aspects of the stress response itself. In the absence of GCs, stress responses – high blood pressure, increased heart rate, and fever – are unbridled and could well be fatal. Essentially, GCs return activated blood and other cells to their quiescent state so that they stop producing the cytokines, PGs, and other inflammatory agents that constitute the host defense mechanism.

Under normal physiological conditions, COX-2 is regulated, among others, by endogenous GCs.

Figure 3 Participation and interdependence of endocrine, immune, and nervous systems in stress. AVP, arginine vasopressin; COX-2, cyclo-oxygenase-2; CRH, corticotropin releasing hormone; PGs, prostaglandins.

Whether the GC surge during stress – a pathophysiological state – affects concomitant PG synthesis has been examined using the rather crude technique of adrenalectomy (ADX) and, more recently, with GC-receptor antagonists such as RU486 (mifepristone). GCs do indeed moderate stress-induced PG production because PG synthesis is elevated in the absence of viable GCs and is reduced again by exogenous dexamethasone, but not by EPI, which is also lacking after ADX.

In the brain, suppression by GCs of PGE₂ along the HPA axis presents an interesting negative feedback response because at least one of the noradrenergic neural circuits leading to ACTH release is mediated via PGE₂. This PGE₂ is stimulated by circulating IL-1, and pro-inflammatory cytokines released into the plasma are also suppressed by GCs. Thus, GCs prevent their own stimulation. The inhibition of IL-1- and PGE₂-induced GCs by GCs could be part of a mechanism for the negative feedback between ACTH and GCs.

In general, and left to themselves, COX-2-stimulated PGs are injurious (they support inflammation allergy). The repression of COX-2 puts GCs into their familiar role of damage control by holding the body's stress response in check and trying to restore homeostasis.

ATP-Independent Proteases

Glossary

- AAA+ proteins** A large family of proteins with ATPase capacity that participate in many cellular processes: AAA stands for ATPases associated with various cellular activities.
- Archaea** One of the three main evolutionary lines of descent or phylogenetic domains. The archaeal organisms are prokaryotes.
- Bacteria** One of the three phylogenetic domains. This domain includes all prokaryotes except archaea.
- Chloroplast** An organelle present in plant cells and photosynthetic protists capable of using

light as source of energy by means of green pigments (chlorophyll) to synthesize carbon compounds from carbon dioxide and water. It is evolutionarily related to cyanobacteria.

Clp

From caseinolytic protease, designates a large family of related enzymes that are also related with the Lon proteases and are present in bacteria, archaea, and eukaryotic organelles.

Eucarya
(*eukarya*)

One of the three main phylogenetic domains. This domain includes all the eukaryotes.

Mitochondrion

An organelle present in animal and plant cells capable of using oxygen to generate energy (aerobes); it synthesizes most of the cellular ATP via oxidative phosphorylation. It is evolutionarily related to the alpha-purple bacteria.

Organelle

A component of eukaryotic cells that resides within the confines of the cell membrane, in the cytosol, but is separated from the cytosol (subcompartment). Organelles contain many components with specialized functions that define their roles, e.g., respiration for the mitochondrion and photosynthesis for the chloroplast. Some organelles are considered to be derived from bacteria that entered into the eukaryotic cell, or its precursor, early in evolution.

Protein Homeostasis

A normal cell has many groups of proteins with distinctive functions. The members of each group must be in their native, functional conformation and within their physiological range of concentration if the cell is to remain fully functional and healthy. Maintenance of all proteins within their physiological conformations and concentration ranges, i.e., protein homeostasis, is achieved by a variety of means. Among these means are those that aim at assisting the nascent polypeptides to fold correctly, namely to achieve a native conformation, or to refold when the mature protein is damaged (unfolded) by stressors such as a sudden increase in temperature (heat shock), or a change in pH or in salinity. Molecular chaperones, discussed in other parts of this Encyclopedia, play a central role in protein folding and refolding.

Another aspect of protein homeostasis is the elimination of damaged molecules that are not repairable by the chaperoning systems, or the degradation of normal molecules that have become unnecessary to the cell after they have carried out their specific functions. Enzymes called proteases, usually forming large multimolecular assemblies such as the proteasome, play a central role in protein degradation and elimination, as discussed in this chapter. Thus the chaperoning and protein-degrading systems are two complementary arms of the whole mechanism responsible for protein homeostasis.

The Archaeal Proteasome

In archaea, the proteasome seems to be the central, if not the exclusive, energy-dependent protease. In contrast, the other prokaryotes, the bacteria, have several of these proteases, such as Lon and Clp (caseinolytic protein; discussed later), and some bacterial species have a proteasome in addition. In fact, the proteasome of one of these bacterial species, *Mycobacterium tuberculosis*, has been shown to be crucial for its survival in the face of stress.

Archaea have a 20S proteasomal particle, with the same overall structure as the eukaryotic counterpart. This overall structure also resembles that of the multimeric chaperonin complex GroEL/S typical of bacteria but also found in some archaea and in eukaryotic cell organelles. All of these complexes are barrel-shaped and have sevenfold rotational symmetry of the subunits arranged around a central cavity, which is accessible only from the ends. Despite the morphological similarities between the archaeal 20S proteasome and the folding chaperonin machine GroEL/S, these complexes differ in several important aspects,

reflecting their very different roles and mechanisms of action. One of the key differences is the size of the mouth of the chamber in its opened state: the mouth in GroEL/S is about four times bigger than that in the proteasome. This difference is very important, because the gate's diameter plays a crucial role in the selection of what goes into the chamber and what is kept outside. Simply on the basis of maximum gate size, we see that entry into the destruction chamber of the proteasome is a highly selective process, allowing the access of only linearized polypeptides brought near by a specific mechanism that includes the attachment of a defined tag to the polypeptide. All of these selection mechanisms operating together determine exactly which polypeptide from among the very many in the intracellular molecular soup will make its way toward destruction. Obviously, a number of mechanisms seem to have evolved in the direction of preserving intracellular structures, a fact that is manifested most evidently in the positioning of the enzymatic sites. These occur inside a chamber without any possibility of digesting surrounding molecules, except those that are allowed inside after careful screening, selection, and preparation.

The archaeal 20S proteasome is composed of 28 subunits, which are related in primary structure and can be classified into 14 families encompassing two superfamilies, alpha and beta. The alpha subunits oligomerize to form the two outer rings, one on each end of the central barrel, i.e., the proteasome core that contains the proteolytic chamber and is formed by two rings of seven beta subunits each. Thus, the similarities with the 20S particle from eukaryotes are evident.

Archaeal and bacterial 20S proteasomes have two to four different subunits (isoforms) in each ring, depending on the species. In contrast, all subunits differ from one another in the eukaryotic proteasome. It should be mentioned, however, that studies in progress are demonstrating more variants of archaeal proteasome subunits, and it is becoming apparent that some species have more isoforms than others. Furthermore, studies in archaea, bacteria, and eukaryotes suggest that certain species, or perhaps many species, have more than one type of 20S particle, each built differently, using different isoforms, and probably having distinct roles. This may be inferred from the fact that in eukaryotes each subunit uniquely occupies a defined position in the ring, suggesting strict control of function and great specialization of the overall structure. Thus, the discovery of distinct types of 20S particles should not be surprising, considering the array of roles that the proteasome plays in a variety of cellular processes.

The archaeal proteasome does not have a 19S particle, in contrast to the eukaryotic 26S proteasome, but it does have a regulatory cap. The archaeal proteasome regulatory factors are called proteasome-activating nucleotidases (Pan), and they are gathered at the entrance of the 20S particle in a manner reminiscent of the 19S particle structure in eukaryotes. The eukaryotic 19S particle has two sections, a lid and a base, the former composed of eight subunits lacking ATPase capacity. These subunits are termed regulatory particle non-ATPases (Rpn). The base has at least six ATPase subunits, which belong to the AAA+, type I proteins, and are called regulatory particle triple A proteins (Rtp). In addition, the base has other subunits that are of the Rpn type. The archaeal regulatory structure, which sits on the alpha rings, is built of Rpt homologs, termed Pan.

AAA+ proteins are proteins involved in many cellular processes, which justifies their name: ATPases associated with various cellular activities, or AAA+.

The final steps of proteolysis, after the proteasome has concluded its work, involve the giant protease TRI (tricorn), which digests the oligopeptides emerging from the proteasome to tri- and dipeptides. These are finally cut into single amino acids by the TRI-interacting factors (peptidases) F1, F2, and F3.

The proteasome in archaea may cooperate with membrane-associated proteases, such as the Lon protease, to translocate and degrade membrane-associated proteins.

Other Proteases in Archaea

Archaea, like bacteria and eukaryotic organelles, possess Clp- and Lon-related proteases. The proteolytic systems of archaea display features that combine bacterial and eukaryotic elements. This duality is just another example of the many structures and functions found in archaea, which seem to be a mixture of bacterial and eukaryotic components, such as those observed in the chaperoning systems and in the gene regulatory machinery.

Compartmentalized Proteases in Bacteria

There are at least five ATP-dependent compartmentalized proteases in bacteria. These bacterial proteases have counterparts in eukaryotic organelles, e.g., mitochondria and chloroplasts. The role of these proteases is to maintain the pool of cellular proteins, such that each species of proteins is present within its physiological range of concentration, and all molecules are in their native, functional conformations. Proteases contribute to this protein homeostasis

by eliminating protein molecules that are abnormal or those that are normal but have become unnecessary, dispensable, after they have done their work and that may interfere with the normal functions of the cell if allowed to stay around. Hence, these proteases are capable of demolishing tertiary and quaternary structures (e.g., they can disassemble multimeric complexes) and degrading their components.

Structure

The active protease structure (i.e., the proteolytic machine that recognizes the client polypeptides marked for degradation, prepares them and delivers them to the proteolytic sites, digests them, and releases the degradation products into the cytoplasm) is a large, barrel-like multimolecular complex. Like the proteasome, the basic bacterial protease structure is composed of multimeric rings stacked coaxially to enclose a central, cylindrical chamber, which is open at both ends. Typically, there are four rings; the central two rings contain the proteolytic sites on their inner surface. The peripheral rings, one on each end of the central proteolytic chamber, serve as substrate selectors and also capture the selected client polypeptide, prepare it (e.g., unfold it completely), thread the linearized substrate through the opening of the central cavity, and translocate it into the cavity. All of these activities, performed by the peripheral rings, require energy from ATP; thus, the components of these rings are ATPases. They belong to the large family of AAA+ ATPases.

Subunits

Several subunits are known to constitute the bacterial protease machines: ClpA, ClpB, ClpC, ClpE, ClpP, ClpX, and ClpY(HslU). Three of the main compartmentalized proteases in bacteria are ClpAP, ClpXP, and ClpXQ (or HslUY); these are composed of a protease (ClpP or ClpQ(HslV)) flanked by an ATPase ring formed by ClpA, ClpX, or ClpY(HslU), respectively. These flanking structures are formed by subunits, which are AAA + ATPases and which function in conjunction with the central structure (ClpP or ClpQ). However, they can also disaggregate protein aggregates by themselves.

Some of the genes encoding Clp proteins are stress inducible, for instance, *clpE*, *clpC*, and *clpP* in *Bacillus subtilis*; hence these proteins are members of the large group of stress proteins.

Rings

The subunits, six or seven of them together, associate to form rings with axial symmetry. Four of these rings

stack on top of each other to build the final structure. Since the rings associate coaxially, the final structure resembles a barrel with a chamber, open at both ends.

All of the subunits in each given ring are identical. The central two rings, which delimit the proteolytic chamber, are each formed by seven ClpP subunits. The two peripheral rings are formed by six subunits, either ClpA or ClpX (for ClpAP and ClpXP, respectively), and they sit on the central two-ring core, one on each end of this core. The peripheral rings in each final structure are identical, either ClpA or ClpX rings.

ClpB forms six-membered rings and interacts with the molecular chaperone machine (Hsp70(DnaK)-Hsp40(DnaJ)-GrpE) to form the Clp/KJE complex. This complex is a disaggregating machine capable of dissolving protein aggregates, particularly when these aggregates contain sHsp in addition to denatured polypeptides, which are the initial cause and key components of the aggregates.

ClpC is a stress protein (i.e., its parent gene is induced by stressors) that is apparently necessary for the survival of *B. subtilis* when this bacterium is faced with stressful conditions. ClpC forms complexes with ClpP, and the adaptor protein MecA (discussed later).

The ATPase peripheral rings play important roles when assembled together with the two central protease rings. These roles are substrate selection, capture, unfolding, and threading, and then translocation and delivery to the proteolytic chamber.

Substrate Selection

Proper selection of which protein will be disassembled and degraded is crucial. In the absence of selection, the entire pool of intracellular proteins (millions of them) would be destroyed rapidly and indiscriminately by the many protease machines extant inside the cell at all times. To avoid this chaotic protein destruction, there are essentially two mechanisms: (1) the enzymatically active sites are separated from the surrounding protein soup by the wall of the cylinder and (2) the peptides to be eliminated must have features that distinguish them from all the others and that make them recognizable by the peripheral rings as client polypeptides.

The proteasome of eukaryotes interacts with the ubiquitin system, which is the system for tagging the polypeptides that will then be recognized by the regulatory particle of the 26S proteasome. Bacteria do not have the ubiquitin system, but they do have tagging mechanisms that work under specific circumstances. In addition, the bacterial proteases can directly recognize partially denatured, damaged polypeptides through

signals consisting of stretches of unstructured sequence, usually near one of the polypeptide's ends. Hydrophobic patches, exposed in these unstructured-sequence segments, are the key as signaling elements.

Also, some client polypeptides are tagged by bacterial tagging mechanisms, such as the SsrA tag system. This mechanism operates when defective polypeptides are produced by stalling ribosomes. In this situation, a short signal of 11 amino acids is added to the C-terminal end of the incomplete polypeptide. SsrA targets the client polypeptide for degradation by ClpXP, ClpAP, and other proteases; it is not specific to any one of them.

Adaptors

Adaptors are proteins that activate proteolytic machines, or that facilitate proteolysis by these machines, by bringing together client polypeptide and machine. The SsbB adaptor joins SsrA-tagged polypeptides together with ClpX (an ATPase) and thus enhances translocation of the client polypeptide into the ClpP proteolytic chamber. Other adaptors are Mub and MecA; the latter interacts with ClpC. MuB inhibits degradation or disassembly of certain potential client polypeptides by occluding the degradation signals present in their sequences.

Another adaptor is ClpS, which interacts with ClpAP to form the ClpAPS complex, a very competent and active protease.

Membrane-Associated Proteolytic Machines in Bacteria

In addition to the protease complexes discussed previously, all of which are in the cytoplasm, bacteria have other protease machines that are associated with their membranes. These machines carry out the degradation of membrane-associated client polypeptides. One of these machines is FtsH(HflB), which forms a very large complex (holoenzyme) with HflKC. FtsH also cooperates with the membrane-integrated metalloprotease HtpX for processing of metal-containing proteins.

Proteases in Cyanobacteria, Mitochondria, and Chloroplasts

In the cyanobacterium *Synechococcus elongatus*, several proteases, Clp-1, Clp-2, Clp-3, and ClpR, and the adaptor ClpS, have been identified. ClpS interacts with ClpA to form ClpAPS, as in other bacteria. Related proteases are found in the chloroplast, presumably evolutionarily related to those found in cyanobacteria.

Mitochondria, which are considered to be derived from ancient alpha purple bacteria – i.e., the ancestors of today's alpha purple bacteria – possess several proteases, including members of the two main AAA+ATPase families. These mitochondrial ATPases are associated with the inner membrane. In the mitochondrial matrix, there are homologs of the bacterial ClpB, ClpX, and Lon, named mtHsp78, mtMcp1, and mLon, respectively. Like their bacterial counterparts, these mitochondrial proteases form a proteolytic chamber with two stacked rings each made of seven identical subunits, and two regulatory rings, one at each end of the core proteolytic chamber, composed of six identical rings, which are distinct from those in the central core rings.

ATP-Independent Proteases

In addition to the ATP-dependent proteases discussed previously, there are others that do not require ATP. For example, one such group of proteases is the DegP (HtrA) family of serine proteases, which encompasses nearly 2000 members. They are widespread and are highly conserved in sequence, being present in the periplasmic space of Gram-negative bacteria and in the ER and chloroplast of eukaryotes.

Interestingly, DegP in the bacterium *Escherichia coli* has either chaperoning or proteolytic ability, depending on the temperature. At physiological temperatures, DegP functions as a chaperone, but at high temperatures it becomes a protease. Like the ATP-dependent proteases, DegP forms oligomeric rings (three subunits per ring) that stack on each other, coaxially, and thus form pairs of hexameric complexes enclosing a central cavity.

Glossary

<i>ATP-dependent protease</i>	A protease that requires energy from ATP hydrolysis to perform its functions.
<i>Client polypeptide</i>	A protein destined for degradation, proteolysis (the protease substrate).
<i>Cofactors</i>	Molecules (usually proteins) that cooperate with chaperones in directing the client polypeptide to the protease, and in preparing it (e.g., unfolding it) so that the protease can receive it for digestion.
<i>Protease</i>	An enzyme that digests proteins, breaking them down into components of various lengths and ultimately producing, in many cases, single amino acids. Different proteases differ in complexity: some are formed by a single molecule, whereas others are assemblages of several molecules.
<i>Proteasome</i>	An example of a proteolytic machine, typically present in the cytosol of eukaryotic and archaeal cells, and also in a small number of bacterial species.
<i>Proteolytic machine</i>	A protease that is a multimolecular assembly, in which each component plays a role in the series of events leading to protein digestion and release of cleavage products.
<i>Self-compartmentalized protease</i>	A proteolytic machine that has its active proteolytic sites inside a cavity, inaccessible to surrounding molecules, and thus requiring an active mechanism for entry of the substrate into the cavity for digestion.
<i>Ubiquitin-proteasome system (UPS)</i>	A protein-degrading system involving the proteasome and a series of enzymes. These enzymes are the ubiquitins (or other

Introduction

Small vs. Large Proteases

Protein homeostasis requires production of polypeptides as well as their regulated destruction, when they are no longer needed or are defective. Molecular chaperones play key roles in both the production of functional proteins and the destruction of useless ones. However, the central players in the destruction phase are the proteases. These enzymes occur, like the chaperones, in every cell and cell compartment in all organisms.

Proteases encompass a wide range of structures, from monomeric hydrolases to multimolecular, giant machines with molecular masses on the order of 1 million Daltons. The large molecular assemblies are self-compartmentalized and have their proteolytic sites inside a central chamber that can be reached only by selected substrates.

This article deals with the large, self-compartmentalized, multimolecular proteolytic machines in the three domains of life: archaea, bacteria, and eucarya (or eukarya).

A General Outline of the Process of Proteolysis

Proteins are, in general, degraded via a series of steps: (1) tagging, i.e., the polypeptide destined for degradation must have a tag, which makes it recognizable by the proteases or by the molecules that will direct the polypeptide to the protease; (2) unfolding, which is usually done via an ATP-dependent mechanism by specific components of proteases, such as Lon/Clp in bacteria and the 26S proteasome in eukaryotes (since at this stage the main event is the unfolding of the polypeptide, the molecules that do the unfolding are called unfoldases); (3) ATP-dependent proteases perform the initial enzymatic attack, generating oligopeptides with fewer than 30 amino acids; (4) these oligopeptides are then further digested by endopeptidases, tripeptidyl peptidases, and dipeptidyl peptidases, yielding still shorter oligopeptides (fewer than 10 amino acids long); and (5) these very short oligopeptides are finally digested into still shorter oligopeptides and single amino acids by aminopeptidases, carboxypeptidases, and di- and tripeptidases. Some of these proteases, e.g., TRI (tricorn) and TET (tetrahedral aminopeptidase), are large multimolecular

complexes like the proteasome. For example, TRI, which is present in some archaea and some bacteria (eukaryotes have in the cytosol a protease, tripeptidyl peptidase II (PPDII), which may be the functional equivalent of TRI), takes the oligopeptides produced by the proteasome and digests them to tri- and dipeptides, which are subsequently cleaved into single amino acids by peptidases called TRI-interacting factors F1, F2, and F3. In summary, unfoldases, the proteasome, TRI, and TRI-interacting factors constitute a multimolecular disassembly line. This general schema applies also to other protein-degrading complexes, some of which are discussed in this article.

Protein-Folding and Protein-Degrading Multimolecular Machines

Polypeptides misfolded because of a structural defect (mutation or posttranslational modification) or unfolded because of stress, as well as incompletely folded (nascent) normal polypeptides, in the cytosol confront a dangerous, highly competitive environment, mainly due to overcrowding. All of these kinds of polypeptides tend to entangle, stick to one another, and form aggregates and precipitates, which can be irreversible and toxic to the cell.

As the misfolded or unfolded polypeptides appear in the cytosol, they encounter the molecular chaperone machine formed by three major teammates, the proteins Hsp70(DnaK), Hsp40(DnaJ), and nucleotide exchange factor. The latter is GrpE (glucose-regulated protein E) in prokaryotes, and BAG-1 (BCL2-associated athanogene, where BCL2 stands for B cell lymphoma 2) or HspBP1 (Hsp70-binding protein 1) in eukaryotes. After this encounter, the polypeptide follows one of two alternative pathways, either toward folding or toward degradation, depending to some extent on its own characteristics and on which cofactors join the chaperone machine. In the eukaryotic cytosol, Hip (Hsc70-interacting protein) and Hop (Hsp70/Hsp90-organizing protein) promote folding, whereas BAG-1 and CHIP (C-terminus of Hsc70-interacting protein) direct the polypeptide toward degradation. In both cases, the polypeptide ends up inside a barrel-shaped chamber.

The folding and proteolytic machines are multimolecular assemblies with a central cavity or chamber. In the prokaryotes bacteria, the folding machine is the complex GroEL/S, and in the eukaryotic cytosol it is the CCT (chaperonin-containing TCP-1, also called TriC for TCP-1 ring complex, where TCP stands for tailless complex polypeptide). An equivalent of CCT, named thermosome, occurs in the prokaryotes archaea. In addition, some archaeal species also have GroEL/S-like bacteria.

The proteolytic machine in bacteria is the Clp complex, whereas in the eukaryotes and archaea it is the proteasome: 26S in the former and 20S in the latter. The organelles of the eukaryotic cell also have folding and proteolytic machines; for example, the mitochondrion has equivalents of the bacterial Clp complex for proteolysis, and it harbors equivalents of GroEL and GroES for protein folding.

The Protein Degradation Pathway Involving the Ubiquitin-Proteasome System (UPS)

In the eukaryotic cytosol, the pathway toward degradation includes various steps and involves diverse components. Initially, the molecular chaperone machine goes into action, and then the cofactors BAG-1 and CHIP interact with the machine and with the next group of participants in the pathway leading to the proteasome. This group is the ubiquitin system.

Ubiquitins

In order for a polypeptide that must be degraded to reach the proteasome, it must first be tagged so that the machine can recognize it. The tag is the ubiquitin molecule, and the tagging is done by the ubiquitin system, which consists of diverse enzymes sorted into three groups, E1, E2, and E3. The E1 are ubiquitin-activating enzymes that prepare ubiquitin for interaction with a carrier, the E2 ubiquitin-conjugating enzymes. E3 ubiquitin ligases bring together the polypeptide destined for degradation (substrate or client polypeptide) and E2, at which point the ubiquitin molecule is attached (ubiquitylation) to the client polypeptide. The proper tag that indicates proteolysis is composed of a chain of at least four ubiquitin molecules; peptides tagged with one to three ubiquitins are directed toward other cellular processes and not to degradation by the proteasome (although they may be directed toward degradation by the lysosome). It must be emphasized that ubiquitylation is widespread in the cell and participates in many processes distinct from protein degradation: cell cycle, DNA repair, regulation of gene transcription, apoptosis, and others.

Ubiquitylation

Ubiquitin is a 76-amino-acid polypeptide, and ubiquitylation occurs via formation of an isopeptide bond between an internal lysine of the substrate and the C-terminal glycine (glycine 76) of ubiquitin. Successive additions of more ubiquitins to form a polyubiquitin chain of at least four units, i.e., a good signal for the proteasome, use the same mechanism

and bond type, but the ubiquitin residues involved are glycine 76 and lysine 48: new ubiquitins are attached to an internal lysine of the last ubiquitin molecule in the chain. A polyubiquitylated substrate is then recognized by the proteasome.

Chaperones and Cofactors for Protein Degradation

A pivotal component of the chaperone machine, and thus of the folding and degradation pathway, is Hsp70. This molecule has segments, motifs or domains, that interact with the other components of the machine and, most importantly, with the client polypeptide in need of assistance for folding or refolding, and also with the polypeptide beyond recovery that must be degraded.

The client polypeptide usually displays hydrophobic residues that, in a folded, native protein, lie in the interior of the molecule, inaccessible to other molecules in the immediate surroundings. Incompletely folded, partially unfolded (denatured), and misfolded polypeptides expose hydrophobic patches on their surface, and these attract Hsp70, which has a peptide-binding domain. This domain is flanked, in the linearized Hsp70 sequence, by an ATPase domain on the N-terminal side and by a lid on the C-terminal side, including the sequence glutamate-glutamate-valine-aspartate (EEVD) at the C-terminus.

The N-terminal section of Hsp70 functions as an ATP-binding and ATPase domain; in addition, it is bound by a number of cochaperones or cofactors of the BAG family (e.g., BAG-1 through 6 and HspBP1) and by Hip. With its C-terminal domain, Hsp70 can bind CHIP and Hop.

BAG-1 functions as a nucleotide exchange factor. The various BAG proteins each have on their C-terminal halves the BAG domain that enables them to bind Hsp70 as well as several other proteins (since they participate in a number of cellular processes). In addition to the BAG domain situated near the C-terminus, BAG family members have a ubiquitin-like domain in the middle of the molecule. This domain can bind to the proteasome and can thus direct a client polypeptide already bound to Hsp70 toward degradation.

CHIP has a tetratricopeptide repeat (TPR) domain with several copies of the TPR in its terminal half, a U box near its C-terminus, and a coiled-coil motif in between. This latter motif participates in protein-protein interactions, whereas the TPR domain is involved in the interaction of CHIP with the C-terminus of Hsp70, and the U box enables CHIP to act as an E3 ubiquitin ligase. The activity of CHIP mimics that of an E3 ligase: it binds to the Hsp70/substrate

complex and then the E2 molecule Ubc4/5, and it thus facilitates the enzymatic polyubiquitylation of the substrate with the participation of an E2 enzyme.

A TPR motif or domain consists of a series of TPRs in tandem; the TPRs are imperfect repeats of 34 amino acids each. This motif is present in many proteins and participates in a great variety of molecular interactions.

In summary, both BAG-1 and CHIP bind the C-terminus of Hsp70: BAG-1 via its C-terminal BAG domain and CHIP via its N-terminal TPR domain. CHIP directs the client polypeptide to the proteasome in association with Ubc4/5 or in association with Ubc4/5 and BAG-1. Another chaperone, Hsp90, comes into play for other similar processes involving specific substrates, e.g., steroid hormone receptors. Here, the general mechanism is essentially the same as the one just described for those cases in which Hsp90 does not participate.

The Proteasome

The proteasome is one of the large protease complexes that have a central chamber, roughly cylindrical, in which proteolysis takes place. Other examples of similar proteolytic chambers are the Clp complexes that are found in the cytoplasm of bacteria and inside organelles in eukaryotes.

The proteasome has been found in the cytosol and nucleus of eukaryotic cells, in the cytoplasm of archaea, and in the cytoplasm of some bacteria, such as gram-positive actinomycetes (e.g., *Mycobacterium tuberculosis*). The eukaryotic proteasome is identified as the 26S particle, whereas those of archaea and bacteria are identified as 20S particles, according to their approximate sedimentation coefficients.

Structure

The 26S proteasome is composed of two main particles (or subparticles), the 20S and the 19S particles, both of which are polymers typically composed of 28 and 17–19 subunits, respectively. The 20S is the proteolytic particle, whereas the 19S particle is regulatory. In current terminology, 26S particle denotes a 20S particle with one 19S particle on one end and a 20S particle with two 19S particles, one on each end.

The 20S particle is formed by four stacked rings, two alpha and two beta rings, the latter in the middle, and one alpha ring on each end of the central barrel formed by the central beta rings. Each ring in turn is constituted of seven subunits, alpha and beta for the alpha and beta rings, respectively. All of the alpha subunits and all of the beta subunits are related in primary structure, but not identical. These subunits are arranged in rings with a central cavity, and since

the four rings are stacked coaxially in the overall structure, the 20S proteasome can be described as a cylinder, resembling a barrel.

The 19S particle is composed of at least 17 distinct subunits arranged in two complexes (or subcomplexes), the base and the lid. The base subcomplex sits on the alpha ring of the 20S particle and is formed by nine subunits, of which six are ATPases. The lid is distal to the base subcomplex, in contact with the intracellular milieu, and is formed by eight subunits devoid of ATPase capacity.

Role of the Proteasome Subunits and Particles

While the 20S particle is involved in the actual degradation (proteolysis) of the client polypeptide, the 19S particle has other functions, such as (1) recognition and sorting of the client polypeptides, i.e., those correctly ubiquitinated with chains of four or more ubiquitins; (2) opening of the mouth (gate) of the proteasome to allow entry of the substrate; (3) unfolding of the client polypeptide as much as necessary for it to negotiate the entrance to the proteasome, which is very narrow and does not allow passage of folded proteins; and (4) threading of the extended, unfolded substrate through the gate and transfer of it to the alpha ring of the 20S particle and beyond, so that the polypeptide reaches the proteolytic chamber delimited by the central beta rings. All of these steps require energy from ATP hydrolysis, which is why the base subcomplex has six ATPase subunits.

Steps Toward Degradation by the Proteasome

Calling for Destruction

The polypeptide destined for degradation has short stretches (5–25 amino acids) that constitute hydrophobic patches and mark it for destruction. However, the proteasome does not recognize such signals; for this to happen, a tag, the polyubiquitin chain described earlier, must be added to the client polypeptides. There may be exceptions to this rule. It is possible that some E3 enzymes can interact directly with the proteasome or that some client polypeptides can be recognized directly by the proteasome and engulfed for degradation without participation of E1 and E2 enzymes. These would be examples of what is called ubiquitin-independent protein degradation by the proteasome.

Unfolding, Release of Chaperones, Gate Opening, and Threading

The client polypeptide cannot enter the mouth of the proteasome if it is not opened first and if the

polypeptide is not linearized and freed from the chaperones and cochaperones accompanying it before it is offered to the mouth. Thus, a mechanism for unfolding polypeptides operates at the mouth of the proteasome. Chaperone–cochaperone release, polypeptide unfolding, and gate opening are probably functions of the 19S particle, but the mechanism has not yet been elucidated.

Translocation from the Cytosol into the Chamber

The unfolding, threading, and translocation of the client polypeptide are most likely simultaneous events, although unfolding may partially precede threading, which in turn may begin before the start of translocation and proceed during translocation, and the final moments of the translocation may occur after the preceding events have concluded. By this time, the leading end of the polypeptide will have reached the proteolytic chamber, with proteolysis starting immediately. It is possible that even proteolysis begins almost simultaneously with translocation.

Proteolysis

Unstructured, less stable segments of the incoming, extended polypeptide are probably recognized by the proteolytic sites lining the inside of the proteolytic chamber, and digestion starts immediately. This part of the process is not specific. Other steps, preceding the actual digestion inside the proteasome, are selective: they depend on specific interactions between molecules that possess certain markers that make them interact only in certain combinations and, thus, recognize and process substrates with signals that are specific for only one of these combinations. In these steps, the role of the E enzymes is crucial, as is explained later.

Indeed, the proteolytic systems are finetuned so as to avoid indiscriminate digestion of cellular proteins and to steer toward destruction only those that must be eliminated for the good of the cell. The entire protein degradation process is strictly regulated by a number of mechanisms involving the E enzymes and the 19S proteasome components, as well as other mechanisms that insert specific signals on those polypeptides that are not wanted in the cell.

The proteolytic efficiency inside the proteasome appears to be very high, possibly a consequence of a concentration of enzymatic sites and the ease of encounter and contact between these sites and the extended substrate sliding naked, as it were, in close proximity of the sites. The resulting products are oligopeptides of 3–30 amino acids.

Exit of Digestion Products

Oligopeptide exit from the proteasome seems to be regulated, too, perhaps as strictly as the selection and entrance of the client polypeptide. However, little is known of the exit process. We can assume that rapid escape must be avoided, so that there will be no generation of incompletely digested substrate fragments, i.e., incomplete degradation. Likewise, excessive retention of completely digested fragments would have to be avoided lest the proteolytic chamber and the exit gate be clogged; such clogging would slow the flux of the whole process, including the pace of the proteolytic activity.

Processing and Reuse of Digestion Products

The oligopeptides emerging from the proteasome are cleaved into shorter oligopeptides and finally into single amino acids by aminopeptidases, carboxypeptidases, and di- and tripeptidases, e.g., in archaea TRI and TET, which are large multimolecular complexes like the proteasome, and TRI-related proteases in eukaryotes. The amino acids generated are used again in the synthesis of new polypeptides on the ribosome.

The Immunoproteasome

The proteasome also plays a role in immunity: it processes antigen and produces antigenic oligopeptides for display on the cell surface associated with other molecules as required for triggering a certain group of T lymphocytes. This type of antigen processing is the function of a specialized proteasome, the immunoproteasome, which differs in some details from the other proteasome discussed earlier, which is involved in general protein degradation.

Proteasomes at inflammatory sites undergo induction of regulatory subunits in the 19S particle and changes in the proteolytic subunits in the 20S particle: subunits beta1, beta2, and beta5 are replaced by their immuno counterparts, beta1i (LPM2), beta2i (MECL-1), and beta5i (LMP7), respectively. The 20S particle is assembled *de novo* with the immuno and the regular subunits in, for example, cells stimulated by γ -interferon or tumor necrosis factor. The other, so-called constitutive proteasome is present in normal cells and in immunoprivileged locales, e.g., brain tissue.

Proteins that appear as antigens to the organism are degraded in the immunoproteasome, and the resulting oligopeptides (8–10 amino acids long) are transported from the cytosol to the endoplasmic reticulum (ER) with the participation of TAP (transporter associated with antigen processing) proteins. In the ER, the peptides bind MHC (major histocompatibility complex) class I molecules, and the complex is

inserted on the cell surface. This type of antigen presentation is critical for the action of certain T lymphocytes, e.g., cytotoxic T cells recognize and interact with the peptide–MHC complex, which may lead to the lysis of the cells carrying the complex on the surface as a means of eliminating potentially damaging cells.

It is believed that the immunoproteasome generates correct epitopes from the C-terminus of the protein antigen, but other enzymes are needed for generation of N-terminus epitopes. Some of the latter are LAP (leucine aminopeptidase) and ERAP 1 (ER aminopeptidase 1), which, as its name suggests, is associated with the ER.

Proteasome Pathology

The proteasome, and the immunoproteasome, can be defective and can thus compromise cell physiology and health. Since the proteasome is the major protagonist in the elimination of proteins that are not beneficial to the cell, when the proteasome function is impaired or stops, the effects are immediate and considerable. Likewise, failure of the immunoproteasome will have an impact on several functions of the immune system, with repercussions throughout the entire body.

Proteasome inhibition by chemical compounds, genetic defects in the component subunits, and acquired alterations of these subunits have all been shown to result in proteasome malfunction and in pathological accumulation of protein aggregates. This effect can be even more deleterious in proteinopathies (e.g., Alzheimer's, Parkinson's, and Huntington's disease). The pathogenesis of these diseases includes misfolding and aggregation of genetically defective proteins, which form intra- and extracellular precipitates in various tissues, particularly the brain, resulting in cell death. Proteasome failure can only aggravate this pathogenetic sequence. Also, it has been observed that the proteasome suffers alterations as the process of senescence progresses.

The Whole Picture

The diversity of the proteasome is evidenced by the variety of subunits encoded in the genomes already sequenced. Likewise, the conservation of the proteasome is apparent in the similarity among all of the subunits, particularly within a single type, alpha or beta, and in the overall architecture, which essentially consists of stacked rings of subunits assembled together to enclose a central cavity, with axial gates at both ends, in all species known to have proteasome.

In eukaryotes, proteasomes have been found in the cytosol and nucleus, and in association with the ER

and the cytoskeleton. Also, proteasomes have been found in archaea and in some bacteria, as mentioned earlier.

It has been demonstrated, or it is believed based on some experimental data, that the proteasome plays a key role not only in protein quality control as discussed in this article, but also in several other cellular processes, such as the immune response, cell division, metabolism, DNA repair, and control of gene transcription. In these instances, the ubiquitin system also intervenes.

Glossary

<i>Chaperone</i>	Protein that functions to support other proteins or growing polypeptides in a particular conformation.
<i>Cytoplasmic stress</i>	Condition associated with the accumulation of misfolded or damaged proteins in the cytoplasm.
<i>Endoplasmic reticulum (ER)</i>	Subcellular organelle in which newly synthesized secretory, lysosomal, and membrane proteins are processed and folded.
<i>ER stress</i>	Condition associated with the accumulation of unfolded or underprocessed proteins in the ER.
<i>GRP78/BiP</i>	A glucose-regulated 78-kDa ER-resident chaperone induced in response to ER stress.
<i>HRI</i>	Heme-regulated eIF2 kinase that functions to inhibit translational initiation in erythroid cells.
<i>HSP/HSC70</i>	A 70-kDa cytoplasmic chaperone(s) induced in response to cytoplasmic stress.
<i>PKR</i>	An interferon-inducible, double-stranded RNA-activated protein kinase that phosphorylates eukaryotic initiation factor (eIF) 2 to inhibit translational initiation.
<i>PKR-like ER kinase</i>	An ER membrane-spanning eIF2 kinase that phosphorylates eIF2 in response to ER stress.
<i>Proteotoxic</i>	Condition resulting in the misfolding or damage of cellular proteins.
<i>Translational elongation</i>	Process occurring on 80S ribosomes through which amino acids are transferred from aminoacyl-tRNAs to the growing

polypeptide chain sequentially in accord with the internal codons of mRNA.

Translational initiation

Process by which the 80S ribosome complex carrying the initiator tRNA, met-tRNA, and mRNA properly phased at the initiation codon is assembled.

Protein synthesis refers to the biological process whereby amino acids are assembled by peptide bonding into specific polypeptide sequences in accord with genetic blueprints encoded by deoxyribonucleic acid (DNA).

Phases of Protein Synthesis

The overall process of protein synthesis occurs in several phases, each of which is highly complex and generally viewed as a separate field of study.

DNA-Directed Nuclear Transcription of Temporary Ribonucleic Acid Constructs (Messenger RNA) and the Processing of mRNA into Ribonuclear Particles for Movement to the Cytoplasm

Information transfer from DNA to mRNA is reflected by the synthesis of analogous purine/pyrimidine ribonucleotide sequences arranged in triplet groupings (codons) that specify individual amino acids. General features of the mRNA structure include a 5' to 3' phosphodiester linkage of nucleotides, a 5'-methylated guanylate cap, a 5'-untranslated region, a coding region, and a 3'-polyadenylate tail. Nucleotide base pairing produces variable degrees of internal looping and winding. A number of stress-related hormones, including adrenal steroids and thyroxine, alter the synthesis of mRNAs encoding specific proteins. The relationship of these transcriptional alterations to the general slowing of protein synthesis produced by these hormones in many tissues is unclear.

Ribosomal Synthesis of Protein through Translation of mRNA Codons

This process is divisible into two phases: translational initiation, which relates to the loading of ribosomes onto mRNA, and translational elongation, which refers to the linkage of amino acids on the ribosomal surface by peptide bonding to produce a growing polypeptide. Eukaryotic translational initiation involves the binding of the small (40S) ribosomal subunit near the mRNA cap and its subsequent movement

(scanning) in a 5′–3′ direction until it detects the first AUG (initiator) base sequence. This triplet ordinarily provides the starting point for reading additional codons specifying the amino acid sequences for assembling proteins. Initiation is catalyzed by at least nine distinct proteins termed initiation factors (eIF) composed of some 25 assorted protein subunits. A number of these factors are subject to alterations of catalytic activity through protein phosphorylation by various protein kinase activities. Scanning involves an intricate interplay of these initiation factors with the 40S ribosomal subunit and mRNA. The 40S ribosomal subunit is converted to a 43S preinitiation complex by association with eIF3 and with a ternary complex consisting of eIF2, methionyl initiator transfer RNA (met-tRNA_i), and GTP. Binding of eIF4F (a complex of 4E, 4A, and 4G) and eIF4B produces helicase mediated unwinding (melting) of the cap region of mRNA that permits cap-proximal association of the 43S preinitiation complex. Stabilization of this complex with subsequent scanning of the ribosomal subunit to the initiator AUG appears to require at least two additional factors, eIF1A and eIF1. Upon binding of the anticodon of met-tRNA_i to the initiator AUG by codon–anticodon base pairing, eIF5 stimulates hydrolysis of the GTP associated with eIF2. This hydrolysis is associated with the binding of the initiator met-tRNA_i at the 40S P-(peptidyl binding) site, the release of all initiation factors from the 40S ribosomal subunit, and the binding of the large (60S) ribosomal subunit to form an 80S ribosome competent of performing peptide chain elongation.

Translational elongation involves the addition of amino acids to the growing peptide chain as specified by the sequence of mRNA codons occurring after the initiator AUG. The process requires two elongation factors (eEF) and a series of transfer RNAs, each of which possesses a specific anticodon and is subject to enzymatic aminoacylation with a specific amino acid. Peptide chain assembly proceeds through eEF1-mediated binding of aminoacyl-tRNA molecules to a binding site (A site) on the ribosome such that the anticodon of the tRNA associates with the codon of the mRNA. The carboxyl end of the peptide chain (or the initiator methionine) of the tRNA in the P site is uncoupled from the tRNA and is covalently linked by peptide bonding to the amino group of the aminoacylated tRNA in the A site. Peptide bonding is catalyzed by a peptidyl transferase activity associated with the ribosomal RNA of the 60S subunit. In conjunction with the hydrolysis of GTP, eEF2 supports the translocation of the resultant peptidyl-tRNA from the A site to the P site and the movement of the ribosome three nucleotides (1 codon)

along the mRNA molecule. The A site is then available for binding another aminoacyl-tRNA in accord with the specificity of the next codon on mRNA. The process of peptide bond formation and ribosomal movement continues until a stop codon (UAA, UAG, or UGA) is reached on the mRNA. In conjunction with a release factor, the peptidyl transferase catalyzes the hydrolysis of the peptidyl-tRNA linkage, permitting the release of the completed peptide.

Posttranslational Protein Processing

Newly synthesized polypeptides may be released directly into the cytosol or targeted for translocation into the endoplasmic reticulum (ER) by a short series of amino acids at the amino terminal end of the protein termed the signal peptide sequence. In either event the polypeptides are biologically inactive until folded to proteins with specific three-dimensional structures. The development of biological activity frequently requires the binding or covalent linkage of various prosthetic groups and the association of polypeptides into proteins consisting of multiple (multimeric) subunits. Cotranslational protein folding in the cytoplasm (cytosol plus mitochondria) is assisted by various protein chaperones, including a series of proteins termed heat shock proteins (HSPs) that are induced by conditions that damage cytosolic proteins. Protein folding associated with the ER occurs simultaneously with contranslational translocation and is assisted by various ER resident chaperones, including GRP78/BiP, GRP94, protein disulfide isomerase, calnexin, and others. The signal peptide is normally removed by an endopeptidase. Some proteins are retained in association with the ER membrane, frequently looped back and forth between the cytosolic and luminal faces of the ER in up to seven-fold membrane-spanning units. These proteins are integral to the synthesis of new membrane. A large fraction of the protein processed within the ER lumen is destined for extracellular secretion. These proteins are frequently stabilized by various types of glycosylation, disulfide bond formation, the oxidation of specific proline residues, and assembly into multimeric proteins. Disulfide bond formation is supported by an ER redox potential that is relatively more oxidizing than that of the cytoplasm. Protein processing is also supported by the high Ca²⁺ content of the organelle. Proteins that meet certain folding criteria move by vesicular transport to the Golgi for additional modification, whereas misformed proteins are targeted for degradation. Inhibitors of ER protein processing that slow protein trafficking to the Golgi result in the induction of some chaperones, most notably GRP78 and GRP94.

Regulation of Translational Initiation

The regulation of translational initiation involves the selection frequency of specific mRNA transcripts for translation and alterations in the rates of ribosomal loading on the transcripts.

Frequency of Transcript Selection

Selection frequency governs the frequency at which individual proteins are synthesized in preference to other proteins. This parameter is affected by the relative abundance of each species of mRNA transcript, which in turn is a function of rates of mRNA transcript turnover, by the recruitment of transcripts from ribonuclear particles into active translation, and by the susceptibility of the transcript to cap-proximal melting by the eIF4 complex, permitting loading of 43S preinitiation complexes. Interaction of the cap-binding protein, eIF4E, is influenced by the 5' leader structure of mRNA such that differential rates of utilization occur with different species of mRNA. The activities of various components of the eIF4 complex, including 4E and 4G, are increased by protein phosphorylation occurring in response to mitogens and hormonal growth factors. Two factors, 4E-BP1 and 4E-BP2, have been reported to exist that modify the activity of eIF4E. The dephosphorylated form of 4E-BP1 is an inhibitor of eIF4E. Phosphorylation and dissociation of 4E-BP1 occur in response to growth promoters such as insulin and epidermal growth factor, whereas certain viral infections, including polio and encephalomyocarditis virus, result in dephosphorylation of this protein. A number of protein kinase activities participate in these phosphorylations in cell-free preparations, including protein kinases A and C, S6 ribosomal protein kinase, and certain kinases for which casein serves as a substrate. Continuing efforts are in progress to identify the endogenous protein kinase(s) that catalyzes these phosphorylations. Phosphorylation of either 4E or 4G is associated with increased rates of initiation. While ribosomal loading ordinarily proceeds through mRNA cap-dependent association, it can also occur through internal loading of ribosomes. Internal ribosomal loading is thought to occur on certain mRNA with unusually long 5'-untranslated regions, such as that for GRP78, various HSPs, and some virally derived messages. eIF4E is proposed to promote internal ribosomal loading.

Alterations in Rates of Ribosomal Loading

Formation of the 43S preinitiation complex from the association of the 40S ribosomal subunit with the ternary complex of eIF2, GTP, and met-tRNA, provides a second major regulatory point in translational

Figure 1 The eIF2 cycle.

initiation (Figure 1). The 43S complex subsequently associates with mRNA, scans to the initiator AUG, and binds the 60S ribosomal subunit to form a monosome capable of translational elongation. At this point the eIF2-associated GTP is converted to GDP, and the factor dissociates from the ribosome. Because the binary eIF2-GDP complex does not support the formation of the ternary complex with met-tRNA_i, a subsequent round of initiation requires the regeneration of eIF2-GTP via the catalytic exchange of GDP for GTP. This exchange is accomplished by eIF2B, a factor typically present at low stoichiometric ratios with respect to eIF2. The affinity of eIF2B for eIF2 is increased greatly by the phosphorylation of Ser-51 of the α subunit of eIF-2 by specific eIF2 kinase activities described later. Increased phosphorylation of eIF2 α is recognized to mediate the translational repression occurring in mammalian cells subjected to a wide variety of physical, chemical, and nutritional stresses. A 20–30% increase in the phosphorylation of eIF2 α is frequently adequate for the sequestration of eIF2B into an inactive complex such that recycling of eIF2 is largely inhibited. Cells, however, tend to vary somewhat in their relative contents of eIF2B and eIF2 and in the degree of eIF2 α phosphorylation required for translational suppression. There is reason to suspect that eIF2B may be subject to additional regulatory inputs. For example, the catalytic activity of the factor is thought to be increased by an insulin-mediated phosphorylation.

Phosphorylation of eIF2 at Ser-51 is catalyzed by four well-characterized protein kinases termed GCN2, PKR, PERK, and HRI. These enzymes comprise a distinct class of protein kinases that share significant sequence homology in their catalytic domains. GCN2 appears to be expressed selectively in yeast and is activated by amino acid starvation. PKR is distributed broadly among mammalian cell

types, inducible by interferon, and activated by low concentrations of double-stranded RNA and by certain viral RNAs. PKR is thought, therefore, to mediate the antiviral effects of interferon. As described later, PKR appears to phosphorylate eIF2 during cytoplasmic stress. PERK functions as an ER membrane-spanning eIF2 kinase that mediates eIF2 phosphorylation during ER stress. The cytoplasmic domain of PERK possesses catalytic activity whereas its luminal domain is thought to sense ER stress. HRI, the heme-regulated inhibitor kinase, is activated by heme deficiency and is expressed predominantly by erythroid cells. Both PKR and HRI undergo an autophosphorylation and dimerization during activation. While less well characterized, PERK probably undergoes similar modifications during activation. PKR, which resides on 60S ribosomes bound to the cytosolic face of the ER, may be capable of cross-dimerizing with PERK.

Most mRNA actively engaged in translation load multiple ribosomes and therefore sediment as polyribosomal assemblies during density gradient centrifugation. The rate of ribosomal loading in conjunction with the rate of peptide bond formation determines the overall rate of translation and the polyribosomal content of cells. Polyribosomal content and size tend to increase whenever the rate of peptide chain elongation is rate limiting with respect to initiation. While some additional recruitment of mRNA from ribonuclear particles into polyribosomes may occur through the phosphorylation and activation of the eIF4 complex in response to mitogens or growth factors, it is unclear that sufficient initiation factors and ribosomal subunits are generally available on a short-term basis to support large increases in initiation through this mechanism. Growth factors also have the potential to alter peptide chain elongation rates through the phosphorylation and activation of eEF1 and, perhaps, through the phosphorylation of ribosomal protein S6 or of various aminoacyl-tRNA synthases. The overall promotion of translation by these modifications as measured by amino acid incorporation ranges on the order of 30–100% depending on cell type over 1–2 h. In contrast, the phosphorylation of eIF2 α in response to various conditions producing cellular stress inhibits initiation by approximately 85–95% within a few minutes in conjunction with reductions in polyribosomal contents. Under these conditions, provision of the 43S preinitiation complex, rather than recruitment of mRNA transcripts through cap melting considerations, becomes rate-limiting on initiation. Suppression of 43S complex formation appears to favor internal ribosomal loading on mRNA transcripts with long 5' leaders typical of various HSPs and of GRP78. Overall, the eIF2 input into the

regulation of translational initiation provides an adjustable braking system that overrides more slowly imposed stimulatory controls. Potential regulation emanating through protein phosphatase activities for the various initiation factors remains largely unexplored.

Cellular Stress and the Inhibition of mRNA Translation

Conditions that either damage intracellular proteins or produce an accumulation of protein-folding intermediates induce cellular stress responses, as defined by the increased expression of one or more HSP or GRP protein chaperones. Protein synthesis is suppressed at translational initiation in a manner that coincides with increased phosphorylation of eIF2 α . Alterations in the content or the degree of phosphorylation of the eIF4 complex have also been observed following varying degrees of cellular damage. Current evidence favors a model in which the rapid sequestration of chaperones by misfolded proteins accumulating during stress signals the activation of an eIF2 kinase (see [Figure 2](#)). Although the subcellular location and degree of protein misfolding determine whether ER resident (GRP) or cytoplasmic (HSP) chaperones are eventually induced, significant misfolding in either subcellular site usually signals increased eIF2 phosphorylation and translational suppression within minutes.

Interruption of ER Protein Processing

ER stress results from an accumulation of under-processed proteins within the organelle that are incompetent of ER to Golgi transport. Accumulation is associated with a variety of treatments that inhibit various processing steps and with genetic variations that result in the expression of unprocessable proteins. Depletion of ER-sequestered Ca²⁺ in response to extracellular Ca²⁺ chelators, Ca²⁺ ionophores, or inhibitors of ER Ca²⁺ uptake interrupts the processing of sugar residues on newly synthesized glycoproteins. Ca²⁺ depletion may also impair the folding of various proteins and the assembly of multimeric proteins in the ER. Mild reducing agents impede the formation of critical disulfide bonds within proteins by shifting the luminal redox potential toward a less oxidizing state such that folding intermediates accumulate. Concentrations of Ca²⁺ depleting agents or reducing agents that are sufficient to inhibit processing do not lower cellular ATP; removal of the agent by washing results in almost immediate restoration of processing and amino acid incorporation. ER stress is also precipitated by the expression of genetically altered unprocessable proteins and by the unbalanced (nonstoichiometric) production of the subunits of

Figure 2 Activation of eIF2 α protein kinase by stress.

multimeric proteins. Tunicamycin, which inhibits asparagine-linked protein glycosylation, and brefeldin A, which produces retrograde coalescence of the Golgi with the ER, result in slowly developing ER stress. These various disturbances of ER function inhibit translational initiation coincident with the phosphorylation of eIF2. Phosphorylation has been ascribed to the activation of PKR and PERK.

A stress response characterized by the increased synthesis of new GRP78 and GRP94 molecules is routinely observed on continued (hours) ER stress. The sequestration of ER chaperones by the under-processed proteins retained within the organelle is thought to initiate the signaling for both translational suppression through eIF2 kinase activation and the induction of new chaperones, albeit by different pathways. The induction of *grp78* mRNA is dependent on the activation of an ER membrane-spanning protein kinase termed Ire1. The ER luminal domains of PERK and Ire1 possess high homology. It is likely that both Ire1 and PERK are inhibited by interactions with GRP78.

Protein Misfolding in the Cytoplasm

Mammalian cells also undergo an acute suppression of mRNA translation during moderate elevations of their optimal ambient temperature or challenge with certain chemical agents. These treatments, which have been termed proteotoxic, promote mis-folding or damage of cytoplasmic proteins. Proteotoxic

agents include sulfhydryl poisons such as sodium arsenite and iodoacetamide, heavy metal cations, and chemical oxidants and free radical generators. The inhibition of mRNA translation in response to most proteotoxic conditions is accompanied by the binding of HSP chaperones to misfolded or damaged proteins, eIF2 phosphorylation, and slowing of translational initiation. Following the initial insult, cells typically express abundant quantities of HSPs of 28–30, 60, 70–72, 90, and 110 kDa mass over the next several hours. These inductions collectively are frequently termed the heat shock response and are accompanied by dephosphorylation of eIF2 and resumption of translation.

The phosphorylation of eIF2 in response to various types of cytoplasmic stress in increased to variable degrees ranging from pronounced phosphorylations with sodium arsenite, low to high phosphorylations with heat stress, and marginal phosphorylations with iodoacetamide. These variations relate to the difficulties in achieving good experimental reproducibility, utilizing conditions that damage cells in a relatively indiscriminate fashion. More stringent conditions that generate relatively complete translational inhibition tend to reduce cell viability, whereas a less rigorous challenge produces only partial suppression. HSP-inducing chemicals observed to promote a rapid phosphorylation of eIF2 include sodium arsenite, Cd^{2+} , Hg^{2+} , *t*-butylhydroperoxide, menadione, and diamide. Arsenite has proven particularly valuable for investigating the regulation of protein synthesis

during cytoplasmic stress as it does not produce ER stress or lower ATP. Reproducible, strong stress responses are produced by the drug as are good recoveries of translational activity during periods of increased HSP expression. While arsenite inactivates many proteins with sulfhydryl groups, inactivation is repaired more readily than that produced by high temperatures, heavy metals, or strong oxidants. Arsenite suppresses translational initiation to degrees that correlate closely with the activation of PKR and the phosphorylation of eIF2. Peptide chain elongation is not affected, energy stores are not depleted, and viability is maintained.

The cytoplasmic chaperone HSC70 interacts with nascent polypeptides in nonstressed cells, most probably to prevent premature folding. In stressed preparations, nascent polypeptides unable to fold properly and mature proteins that experience damaged folding become stably bound to HSC70. Sequestration of this chaperone during cytoplasmic stress, therefore, has been proposed to signal the heat shock response. Inactivation of PKR has been reported to involve interaction of HSP70 with P58, a cellular inhibitor of the kinase. Various HSPs also function prominently in steroid hormone delivery to the nucleus, the regulation of chaperone-dependent protein kinase activities, clathrin uncoating of coated vesicles, and the transport of protein into the mitochondria.

Nutritional Stress and Stress-Related Apoptosis

Amino acid starvation is associated with slowed rates of translational initiation and, at least in yeast, increased eIF2 phosphorylation. The mechanisms signaling phosphorylation under these conditions are unknown, although the depletion of active chaperones may be involved. For example, GRP78 of cultured cells is known to be inactivated by ADP-ribosylation after nutrients in growth media are expended and protein synthetic rates are slowed, eIF2 phosphorylation and translational suppression, attributed to the activation of PKR, have been observed in cells undergoing programmed cell death in response to inflammatory cytokines, growth factor deprivation, and ultraviolet light. The extent to which proteins misfold and stress proteins are induced under any of the just-described conditions is unclear. However, glucose deprivation promotes expression of ER chaperones in cultured cells, presumably as a consequence of decreased protein glycosylation.

Stress and the Activation of HRI

HRI of reticulocyte lysates is activated in response to heat shock, oxidative stress, and addition of

denatured proteins. In lysates the kinase is known to associate with multiple stress chaperones, including HSP90 and HSC70. HSP90 protects HRI during its synthesis and stabilizes the mature kinase such that it can be autophosphorylated and converted to an activatable form without undergoing stress-dependent denaturation. Because HSP90 dissociates on conversion of the kinase to the activatable form, the chaperone does not function in the process by which stress promotes activation. HSC70 also interacts with nascent and mature competent HRI. Unlike HSP90, however, HSC70 remains associated with the fully activatable kinase. Dissociation of this chaperone fosters activation whereas association suppresses activation. In the intact stressed erythroid cell, therefore, sequestration of HSC70 by misfolded proteins may serve to signal activation of HRI, resulting in eIF2 phosphorylation and slowing of protein synthesis. Because development of erythroid stem cells into reticulocytes involves the ejection of the nucleus in conjunction with loss of functional ER, increased expression of ER or cytoplasmic chaperones is not observed in the more differentiated red cell during stress.

The central role of eIF2 kinase in the translational suppression that transpires during viral infection, ER stress, or cytoplasmic stress is modeled in [Figure 2](#). Using this model, misfolded proteins accumulating during stress compete with the kinase for chaperone binding. Dissociation of chaperones, in combination with subunit rearrangements, promotes autophosphorylation and activation of the kinase. eIF2 α is phosphorylated and initiation is slowed. Reversibility of translational inhibition requires reassociation of chaperones to repress kinase activity and a protein phosphatase to dephosphorylate eIF2 α .

Comparable Roles of the Endoplasmic Reticulum and Cytoplasmic Stress Responses in Recovery of Translational Activity

Separate, but closely related, stress response systems exist for the ER, regarding the induction of the GRPs, and for the cytoplasm, pertaining to the induction of the HSPs. As discussed earlier, mRNAs for GRPs and HSPs possess unusual structural features at their 5' ends thought to favor their selective translation during stress. GRP78 and GRP94, the most prominently induced ER stress chaperones, share significant sequence homology with HSP70 and HSP90, respectively. GRP78 is hypothesized to function in early ER protein folding and assembly, in the translocation of proteins from the cytosol to the ER for processing,

and in the retention and degradation of improperly folded proteins. Comparable chaperone activity is exhibited by HSP70 and a closely related form of the protein expressed in nonstressed cells, HSC70. Both prevent incorrect folding of polypeptides during synthesis, permitting delivery to organelles in an unfolded state for translocation. These chaperones may also solubilize or refold denatured or aberrant proteins and/or deliver them to a degradative system. Induction of GRPs or HSPs appears necessary for survival during persistent ER or cytoplasmic stress, respectively.

The induction of either GRPs or HSPs in stressed cells is accompanied by a reduced phosphorylation of eIF2 and a partial resumption of mRNA translation. Induction of either class of stress proteins is sufficient for the development of translational tolerance to subsequent rechallenge of the cells with either ER or cytoplasmic stressors. Cross-tolerance is observed in terms of continued amino acid incorporation into proteins, maintenance of polyribosomal contents, and the lack of increased eIF2 phosphorylation. Translational recovery from inhibition by Ca^{2+} -releasing drugs is partly overturned by antisense oligonucleotides directed against *grp78* mRNA, whereas

overexpression of GRP78 is sufficient for tolerance to translational inhibition and eIF2 phosphorylation in response to ER stress. Presumably various GRP and HSP chaperones inhibit eIF2 kinase(s) through complexing with a critical component(s) of the enzymes or with another protein(s), which affects activity. If so, the sequence homology of GRP78 and HSP70/HSC70 may be important to the putative dual input.

By regulating eIF2 kinase activity, the two stress chaperone systems permit rates of protein folding or processing to be coordinated with rates of protein synthesis through changes in the rate of recycling of eIF2 and of ribosomal loading onto mRNA. The interactions of GRP78 in regulating translational initiation are modeled in Figure 3.

With the exception of their mutual abilities to influence eIF2 phosphorylation, the two stress systems appear to function independently. For example, sodium arsenite does not induce the GRPs nor does it affect Ca^{2+} retention by the ER. Following induction of GRP78 with Ca^{2+} -mobilizing agents, cells remain responsive to HSP induction by subsequent arsenite treatment. Similarly, cells expressing the cytoplasmic stress response remain susceptible to induction of the GRPs. It should be recognized that

the phosphorylation of eIF2 and the inhibition of translation are not mandatory for the induction of stress proteins.

Low concentrations of ER stressors clearly induce GRP78 in the absence of eIF2 phosphorylation or inhibition of translation. Greater degrees of cytoplasmic stress also appear to be required for the signaling of translational suppression than for induction of the HSPs. These findings are consistent with the existence of pathways to slow the synthesis of protein precursors only when processing or folding is seriously impaired.

eIF2 Kinase as a Focal Point for Regulating Protein Synthesis during Stress

The body of available information with nonerythroid mammalian cells suggests that PERK and PKR function together in governing rates of translational initiation in response to various stimuli including, but not limited to, ER and cytoplasmic stresses. HRI, a heme-regulated protein kinase, is unlikely to mediate translational suppression in stressed nonerythroid cells. Because the induction of either HSPs or GRP78 provides cross-tolerance to either ER or cytoplasmic stressors, it seems clear that PERK and PKR interact in some manner, perhaps through cross-dimerization of their respective kinase domains during activation. It is, of course, quite possible that additional homologous forms of eIF2 kinase remain to be discovered. Putative additional stimuli for eIF2 kinase activation could include hormonal or nutritional alterations or treatments that damage cell membranes.

The Ubiquitin-Proteosome System

The Ubiquitin-Proteosome System in the Pathogenesis of Disease

Conclusion

Glossary

<i>26S Proteosome</i>	Large protease complex composed of a 20S proteolytic-containing complex capped by two 19S regulatory particles responsible for degradation of polyubiquitinated proteins.
<i>E3 ubiquitin ligase</i>	Diverse group of enzymes with distinct motifs for recognizing specific substrates that carry out the final transfer of ubiquitin to the bound substrate.
<i>N-end rule</i>	Relates the N-terminal residue to the half-life of an intracellular protein.
<i>Ubiquitin-proteosome system</i>	Major proteolytic pathway for intracellular protein degradation involved in many key cellular processes.
<i>Ubiquitination</i>	Enzymatic process that sequentially covalently links ubiquitin to targeted protein substrates to form a polyubiquitin chain recognized by the 26S proteosome.
<i>Unfolded protein response</i>	Highly specific signaling pathway in the endoplasmic reticulum (ER) that recognizes the accumulation of un- or misfolded proteins caused by disruption of ER homeostasis.

Understanding cellular homeostasis requires knowledge of both synthetic and degradation pathways. Protein degradation, in particular, plays a key regulatory process for many cellular processes. There are two systems involved in intracellular protein

degradation. The lysosomal pathway was first identified, but in the late 1950s, Goldberg and colleagues demonstrated a new type of proteolytic system in lysosome-free reticulocyte cell extracts. This led to the discovery of ubiquitin and the proteosome and the elucidation of the ubiquitin-proteosome system (UPS). The UPS degrades the vast majority (up to 80–90%) of long- and short-lived normal and abnormal intracellular proteins, hence is considered to be the major pathway for intracellular protein degradation. A growing body of evidence shows that this is a highly regulated yet complex system that is central to normal homeostasis, including cell cycle regulation, DNA repair, regulation of immune and inflammatory responses, and cellular response to stress. Proteins targeted by the UPS include mutated and misfolded proteins, cyclins, and tumor suppressors. Derangements of the UPS can lead to many disorders, including malignancies, neurodegenerative diseases, and possible systemic autoimmunity. A better understanding of the UPS process and identification of the components involved in the degradation of key regulatory proteins have led to the development of mechanism-based therapeutics in various diseases.

The Ubiquitin-Proteosome System

Ubiquitin and Ubiquitination

The control of protein turnover must logically, but not necessarily intuitively, be a counterpart to protein synthesis. This dynamic balance, revealed by variability in the degradation rates and half-life of different proteins, relies on the UPS. The proteolysis is energy dependent and specific. Proteins are selectively targeted for degradation by covalent linkage to ubiquitin, a 76-residue protein that is highly evolutionarily conserved in all eukaryotes. The name ubiquitin is a misnomer, having arisen from the original belief that it was found in all cellular organisms. The linkage of ubiquitin to target protein is followed by sequential addition of more ubiquitin moieties to each other to form a polyubiquitin chain that functions as the

recognition signal for a downstream proteasome in the UPS. Poly- or monoubiquitination can be involved in a variety of nonproteolytic functions, such as activating enzymes, modification of histones that regulate transcription, modulation of membrane dynamics, or routing of the tagged proteins to their subcellular compartments. Ubiquitin-binding proteins that have ubiquitin-binding domains recognize some ubiquitinated proteins. Modification of target protein by ubiquitin or a ubiquitin-like protein remodels the surface of target proteins, affecting their stability, interactions with other proteins, activity, and subcellular localization. At least 10 different modifiers have been described in mammalian cells, and conjugation of each modifier to its target has different biological effect.

Ubiquitination Reaction

Ubiquitination of cellular proteins is a highly complex, temporally controlled, and tightly regulated energy-dependent process. The conjugation of ubiquitin is carried out in a cascade reaction involving three enzymes designated E1, E2, and E3 (Figure 1). Ubiquitination begins with the attachment of ubiquitin by E1, also known as the ubiquitin-activating enzyme. Ubiquitin is then transferred to E2, or the ubiquitin-conjugating enzyme. The final step is dependent on one of many E3s (several hundred forms have been identified in the human genome) that are

responsible for catalyzing the addition of ubiquitin to the protein substrate. Chain elongation, or polyubiquitination, can be carried out by the same E3 or by a different ligase, which can be referred to as E4.

Substrate Targeting

The UPS is highly specific and selective. Much of this lies in the diversity of different ubiquitin-protein ligase E3s that can recognize a specific substrate. Many substrates are recognized only after modifications such as misfolding, denaturing, hydroxylation, or phosphorylation. Molecular chaperones such as heat shock protein 70 or chaperon-like molecules such as valosin-containing protein can also act as recognition elements. E3 ligases recognize specific targeting motifs, which can vary from a single amino acid residue to a domain not usually exposed. One of the most important recognition patterns is a destabilizing N-terminal amino acid. A sequence such as arginine and lysine can be a unique feature of a protein, which relates the half-life of an intracellular protein to its N-terminal residue, which has become known as the N-end rule. Phosphorylation of either the substrate or the ligase can also control targeting. Ubiquitin-like proteins can also play a regulatory role by protecting proteins from ubiquitination.

In addition to its substrates, the activity of the ubiquitin system itself can be modulated by a number

Figure 1 Schematic of the ubiquitin-proteasome system. Ubiquitin is added sequentially to targeted substrates in an energy-dependent enzymatic cascade requiring three enzymes, E1, E2 and E3. Polyubiquitinated proteins are recognized by the 26S proteasome. Cleavage produces small peptides and free ubiquitin. Adapted from Kisselev and Goldberg (2001) with permission from Elsevier.

of factors, including thyroid hormones, glucocorticoid steroids, cytokines, and proteins expressed in malignant cells such as proteolysis-inducing factor (PIF). Interestingly, some factors such as interferon gamma (IFN- γ) not only regulate the modification of substrate, including the I κ B family of proteins, but also modify the components of the enzymatic machinery of the ubiquitin system and the proteasome complex. Similarly, protein kinase C and the tyrosine kinase pathway are involved in both the modification of substrates of UPS and phosphorylation of E1 and E2, thereby exerting their activities with high efficiency.

The Proteasome

The ubiquitinated substrates targeted for proteolysis are recognized by a 26S complex cellular structure, the proteasome (Figure 2). This high-molecular-mass protease is also ATP dependent. Degradation of proteins by proteasomes removes denatured, damaged, or improperly translated proteins and regulates the level of proteins in the cells. The 26S proteasome is composed of two subcomplexes. One or two 19S regulatory particles (RPs) cap either or both ends of the barrel-shaped 20S complex, which carries the proteolytic activity, forming 26S and 30S proteasomes, respectively. The 19S RP is responsible for recognizing the ubiquitinated proteins as proteasome substrates, the opening of the orifice in the 20S

complex that allows entry onto the proteolytic chamber and likely the unfolding of the substrate necessary for entry. Within the chamber, proteins are broken down into short peptides. Without the 19S RP, the 20S complex is extremely inefficient in degrading folded protein substrates. The 20S complex is composed of four stacked rings, two identical outer α rings and two inner β rings. Each ring has seven distinct subunits. The β rings contains multiple catalytic sites including chymotrypsin-like sites that are the target of almost all the synthetic and natural inhibitors of the proteasome. The outer two α rings have no known function. Other subcomplexes can cap the 20S complex, creating a polar arrangement that can affect the product generated.

Degradation Products

After the protein has been degraded, the 19S RP removes the polyubiquitin tag from the substrate protein. Degradation in the proteasome generates short peptides that can have different fates. Some are further degraded by cytosolic peptidases. Some can be transported into the endoplasmic reticulum (ER) for binding to MHC class I molecules and cell surface expression. This latter subset of antigenic peptides may arise from proteasome activator PA28 subcomplex capped polar proteasomes that generate peptides trimmed to properly fit the MHC class I binding grooves. In this regard, hybrid proteasomes (19S

Figure 2 Electron tomographic image and structure of the 26S proteasome microscope. The 26S proteasome is composed of the barrel-shaped 20S complex capped by two 19S subcomplexes. The 19S regulatory particle recognizes the polyubiquitin tag on targeted substrates and unfolds the substrate to enter the proteolytic chamber. RP-20S proteasome-PA28) may have unique value during immune responses. Peptides are not always the final product of the UPS, as longer, biologically active proteins can be generated from precursors. Free, reusable ubiquitin is also generated. Deubiquitylating enzymes catalyze this reaction.

The Ubiquitin-Proteasome System in the Pathogenesis of Disease

The Role of the UPS in Stress and Disease

Regulation of protein turnover has an important role in various cellular functions, and alterations can lead to many diseases. Viruses have evolved proteins that can exploit this system to their advantage by either enhancing or avoiding ubiquitination. The unfolded protein response (UPR) is a highly specific signaling pathway in the ER that recognizes the accumulation of un- or misfolded proteins caused by disruption of ER homeostasis. Activating the UPR has multiple effects, including enhancing degradation of the luminal content of the ER via the UPS, and has been implicated in numerous disease processes.

Malignancies

Protein degradation via the ubiquitin-proteasome system is an important regulator of cell cycle progression and survival through modulating the function of nuclear factor- κ B (NF- κ B) and pro-apoptotic transcription factor p53. Thus, inhibition of this pathway can be directly cytotoxic and can sensitize several tumor cell types to cytotoxic chemotherapy and radiation. Most of the experience with proteasome inhibition has been gained through work done in this disease area. Preclinical studies have demonstrated that the proteasome inhibitor bortezomib decreases proliferation, induces apoptosis, enhances the activity of chemotherapy and radiation, and reverses chemoresistance in a variety of hematologic and solid malignancy models *in vitro* and *in vivo*. Bortezomib was the first proteasome inhibitor to enter clinical trials. In two phase II trials, bortezomib alone or in combination with dexamethasone elicited durable responses with meaningful survival benefits in patients with recurrent and/or refractory multiple myeloma. In a phase III trial, bortezomib produced significant survival benefits and improved response rates over high-dose dexamethasone at first recurrence and beyond in patients with multiple myeloma. Current studies indicate that bortezomib may serve as induction therapy before stem cell transplantation. In addition, proteasome inhibition with bortezomib also has shown activity and manageable toxicity in mantle cell and other lymphoma.

Neurodegenerative Diseases

Dysregulation of the UPS has been implicated in the pathogenesis of both inherited and acquired neurodegenerative diseases. Accumulation of ubiquitin conjugates and/or inclusion bodies associated with ubiquitin, proteasomes, and certain disease-specific proteins has been demonstrated in a wide variety of neurodegenerative diseases. The list includes neurofibrillary tangles of Alzheimer's disease, brain stem Lewy bodies, the pathological hallmark in Parkinson's disease, Bunina bodies in amyotrophic lateral sclerosis, and nuclear inclusions in CAG repeat expansion disorders such as Huntington's disease, spinocerebellar ataxias, and spinal and bulbar muscular atrophy (Kennedy's disease). This phenomenon is thought to be due to failed attempts of the UPS to process damaged and abnormal proteins, or movement of the proteasome to specific subcellular sites where degradation of abnormal proteins may occur.

There are at least three key players that link aberration in the UPS to the pathogenesis of neurodegenerative diseases. The first is Parkin, a 52-kDa RING finger-containing E3 ligase that ubiquitinates and promotes degradation of several proteins related to the pathogenesis of Parkinson's disease. Mutations in the gene have been found in ~50% of patients with autosomal recessive juvenile Parkinsonism, one of the most common familial form of Parkinson's disease. Second is α -synuclein, a 140-amino-acid residue protein shown to be a major component of Lewy bodies and Lewy neuritis in sporadic Parkinson's disease, dementia with Lewy bodies, and the Lewy body variant of Alzheimer's disease. Third is ubiquitin C-terminal hydrolase (UCH-L1). Mutations of UCH-L1 were discovered in a German family with Parkinson's disease.

The most compelling evidence for the involvement of the UPS in the pathogenesis of Alzheimer's disease derived from the discovery that a frameshift mutation in the ubiquitin transcript resulted in a mutant form of ubiquitin called UBB⁺¹. This mutant has been observed in brains of Alzheimer's disease patients. Expression of UBB⁺¹ in the brain could inhibit the degradation of a polyubiquitinated substrate by the 26S proteasome, leading to accumulation of toxic proteins with neuropathological consequences.

Inflammation and Autoimmune Diseases

Many autoimmune diseases are characterized by immunologically mediated organ damage. Some of these autoimmune diseases may have recognizable environmental triggers, such as infections, but it is not known how or why inflammation is initiated in most and sustained in all. Key to these diseases is the same cells and molecules, such as cytokines, that

are also central to normal immunity. The UPS is now known to regulate many of these, including MHC-mediated antigen presentation, cytokine regulation, and cell cycle, and must therefore also have a role in their pathogenesis and be a logical therapeutic target.

One of the prominent examples for the involvement of the UPS in inflammation is MHC class I antigen processing by antigen-presenting cells (APCs). In addition, the UPS plays a significant role in the regulation of both T cell receptor (TCRs) and costimulatory CD28 signaling through the action of ubiquitin ligases of the Cbl family. CD28 costimulation results in the ubiquitination and degradation of Cbl-b, which eliminates the negative regulators and allows the expression of proinflammatory cytokines and their receptors. However, the most important link between the UPS and inflammation is related to NF- κ B. NF- κ B is a master regulator of many inflammatory cytokine genes, and its activation is mediated through the UPS. NF- κ B is actively inhibited when bound to I κ B. NF- κ B activation follows the degradation of I κ B, which is dependent on ubiquitination of I κ B followed by proteasomal degradation. Hence, alterations in the UPS have profound effects on immune responses, including the regulation of an array of inflammatory cytokines.

INF- γ is a key pleiotropic regulatory cytokine. It controls an inducible proteolytic cascade that provides peptides for MHC class I presentation. Sero-negative spondyloarthropathies (SpA) are a group of diseases characterized by, but not limited to, axial joint inflammatory. Ankylosing spondylitis (AS) is the prototypical SpA. Most patients with AS carry the MHC class I HLA-B27 gene, so its role in disease pathogenesis is an area of intense research. Much interest has been focused on determining the origin and nature of the peptides being presented by HLA-B27 and the cell surface expression of misfolded HLA-B27, key areas in which the UPS is known to play a role.

The UPS is involved in the regulation or induction of apoptosis. Apoptosis has been implicated in both experimental models and patients with systemic lupus erythematosus. Altered clearance of autoantigens is thought to allow for targeting by the immune system and the development of autoimmunity.

The UPS may be involved in the pathogenesis of multiple autoimmune diseases through many different mechanisms. It may therefore be a therapeutic target worth considering. Conversely, targeting the UPS may produce unwanted immunological side effects.

Cardiovascular Diseases

Inflammation, cell proliferation, and apoptosis constitute major feature of atherosclerosis. The UPS

is involved in the development of atherosclerosis through its regulation of these biological pathways. In addition, the UPS is associated with the pathogenesis of acute coronary syndromes through diverse cellular and intracellular targets and modes of actions. Recent experimental evidence indicates that the UPS is functionally active in early atherogenesis despite increased oxidative stress mimicking the initiation stage of atherosclerosis. The pathophysiological role of the UPS in the proliferative aspects of cardiovascular disease was demonstrated by the intense ubiquitin nuclear staining in intimal thickening lesions. Treatment of cultured vascular smooth muscle cells with proteasome inhibitor has led to a dose-dependent inhibition of proliferation and induction of apoptosis. In rodent models, single-dose local administration of the proteasome inhibitor MG-132 for 5 min after endothelial denudation of carotid arteries reduces neointima formation by 75%. Further, proteasome inhibition led to significant reduction in vascular atrophy in DOCA-salt hypertensive rats.

T cells have been identified as a characteristic inflammatory element of atherosclerosis, which accumulate at the rupture-prone sites of the plaque shoulder regions. The UPS is involved in the pathogenesis of atherosclerosis by regulating the activation of T cells through T cell receptors and costimulatory molecule CD28. The UPS may be involved in foam cell formation as well. In an autopsy-based study, increased expression of ubiquitin/ubiquitin conjugates was colocalized with macrophages and apoptotic cells in the area of the lipid core. It has been shown that the expression of p53 in human atherosclerotic plaques was enhanced, and overexpression of p53 resulted in a significant increase in apoptosis and decrease in extracellular matrix in the cap region. Accumulating evidence indicates a strong association of pro-apoptotic protein p53, ubiquitin, and apoptotic neointimal cells in the cap region of unstable plaques from patients with fatal myocardial infarction.

Conclusion

The UPS is a complex system that controls many important aspects of cell function. The covalent linkage of ubiquitin to protein substrates can selectively and specifically alter their fate through proteolytic and nonproteolytic pathways. Loss of normal homeostasis through many mechanisms, including stress, can lead to aberrant cellular function and disease.

Immunopathology of Psoriasis
Stress – a Triggering Factor in Psoriasis
Psychobiology of Psoriasis
Summary

Glossary

<i>Keratinocytes</i>	Major cell type of the epidermis making up to 90% of epidermal cells. Keratinocytes are shed and replaced continuously from the stratum corneum. The time of transit from basal layer to shedding is approximately one month although this can be accelerated in conditions of keratinocyte hyperproliferation, i.e., psoriasis.
<i>Phototherapy</i>	Light therapy using specific wavelength of light for a distinct period of time. Generally, lasers, fluorescent light, or full-spectrum light are used.
<i>Superantigens</i>	Molecules that stimulate indiscriminately T-cells. The best characterized superantigens are the microbial toxins from <i>Staphylococcus aureus</i> and <i>Streptococcus pyogenes</i> .

Immunopathology of Psoriasis

Psoriasis (PSO) is a chronic, genetically determined inflammatory skin disease with an estimated prevalence of 2% of the northern population. Apart from allergic contact dermatitis and atopic dermatitis, PSO is the most common chronic skin disease. PSO can start at any age; however, disease onset is most frequently observed in the second decade of life. PSO symptomatology is characterized by erythematous and solid skin plaques with sharply defined borders, covered with fine silvery scales. Although not life threatening, PSO can be a disabling disease with a considerable impact on patients' psychological and social well-being. Psoriatics often feel stigmatized and psychologically stressed by the disfiguring skin disease, which can lead to increased anxiety and depression.

The pathophysiology of PSO is not fully understood. However, accumulating evidence suggests that T-cell-mediated autoimmune processes and the action of pro-inflammatory cytokines cause the hyperproliferation of keratinocytes and assume the psoriatic phenotype. The antigenic peptide responsible for the initial T-cell activation in PSO has not been established yet. However, one current model is that bacterial proteins (streptococcal M proteins) resulting from a preceding infection may act as superantigens. Another important process in PSO pathogenesis

is the trafficking of the activated T cell into the skin. Activated T cells generated from psoriatic skin lesions secrete high concentrations of interleukin (IL)-2, tumor necrosis factor (TNF)- α , and interferon (IFN)- γ , indicating a significant role of T helper 1 (Th₁)-mediated inflammatory processes in the psoriatic skin. The significant role of circulating Th₁-derived cytokines is further supported by the finding that TNF- α and IFN- γ increase the infiltration of T cells and other inflammatory cells such as monocytes into the skin. Locally, IFN- γ stimulates epidermal cell proliferation and keratinocyte hyperplasia, leading to the psoriatic phenotype.

Stress – a Triggering Factor in Psoriasis

Although PSO has been conceptualized as an autoimmune disease primarily mediated by an inappropriate function of T cells, it is broadly accepted that psychosocial stress may affect PSO and may trigger the exacerbation of the disease. For example, 31% of PSO patients reported the onset of PSO in times of increased everyday life stress, and for 71%, PSO symptomatology worsened during stressful life episodes. To further evaluate the role of stress in the onset and exacerbation of PSO, psychocutaneous characteristics in PSO sufferers reporting a strong link between psychosocial stress and skin condition (high stress reactors, HSRs) and in PSO patients without any association between stress and PSO symptoms (low stress reactors, LSRs) have been investigated. Clinically, HSRs suffered from a more severe disease, with a distinct distribution of PSO plaques in emotionally charged body regions (i.e., the face, neck, forearms, hands, and genital regions), affecting the patient's physical appearance and sexuality. It has been proposed that exacerbation of the disease may lead to stronger psychological reactions and, thus, may explain the strong psychocutaneous relationship in this patient group. Psychologically, the HSRs tended to rely more on the approval of others and scored higher on depressed anger and hostility. Others have reported increased levels of anxiety, aggression, obsessionality, and depression in PSO sufferers, with the last being linked to pruritus and sleep difficulties. It is of note, however, that the personality pattern described in psoriatics can also be identified in patients with atopic dermatitis (AD), a chronic (allergic) inflammatory skin disease characterized by clinical features similar to PSO such as severe pruritus or disfiguring skin symptomatology. These observations suggest that the personality type described in psoriatics may not be a PSO-specific personality type but, rather, represents a personality pattern linked to a chronic inflammatory and disfiguring skin disease.

The importance of stress in PSO has been further highlighted by reports suggesting that psychological distress affects treatment outcome in PSO patients. In these studies, it was demonstrated that the level of stress may predict the time it took for photochemotherapy (PUVA: psoralen, P, and long-wave ultraviolet radiation, UVA) to clear PSO symptomatology. Accordingly, stress reduction by stress management, relaxation, or cognitive techniques shortened the time it took to clear PSO symptoms by PUVA and, moreover, improved the clinical severity of PSO.

Psychobiology of Psoriasis

So far we have summarized the immunological and psychological factors crucial in the onset and maintenance of PSO. Based on these findings, it remains to be determined how PSO-relevant psychological and immunological processes are linked and, moreover, by which mechanisms stress may affect skin condition in PSO.

Considerable evidence has emerged showing that the central nervous system (CNS) and the immune system are intimately connected, each regulating the other. One major pathway through which the CNS exerts control over the immune system is via the neuroendocrine system. Neuropeptides released by the brain may act directly on immune cells, or they may affect the release of other hormones from endocrine tissues that can modify immunity. Investigating neuroendocrine-immunity communication pathways in PSO patients and, moreover, studying potential aberrations in the interplay between these systems under stressful conditions may give a hint about how stress can trigger inflammatory processes in PSO and exacerbate PSO symptomatology.

In the last decade, an extensive literature has emerged demonstrating the important immunosuppressive and anti-inflammatory role of the hypothalamus-pituitary-adrenal (HPA) axis. Recently, the role of stress-induced HPA axis activation has been specified – an appropriate reactivity of the HPA axis under stress may be necessary to regulate immune function and to prevent an immune response, for example an inflammatory response, from reaching a level that may be damaging to the host. There are some data suggesting a hyporesponsive or hypoactive HPA axis in PSO patients. For example, attenuated cortisol responses to psychosocial stress or diminished urinary cortisol concentrations in psoriatics have been reported. However, other researchers failed to demonstrate reduced cortisol or adrenocorticotrophic hormone (ACTH) responses to stress in PSO sufferers. One factor that may explain the heterogeneous study results may be the acuity or chronicity of the

ongoing inflammatory process in the patient group investigated. There is evidence that normal cortisol levels can be found in chronic nonprogressive PSO characterized by clinical inactivity of chronic plaques, whereas clinically active phases with fresh eruptions were characterized by increased HPA axis activity. These data suggest that it may be useful to consider inflammation in PSO as a dynamic process with different phases of acuity and remission that may be linked to distinct endocrine response patterns.

In general, the increased activity of the sympatho-adrenomedullary (SAM) system in PSO subjects has been described. Studies using standardized psychosocial stressors, including, for example, free speech or mental arithmetic tasks in front of an audience, found significantly increased epinephrine and norepinephrine levels compared to healthy controls. Because elevated responsiveness of the SAM system with significantly increased levels of catecholamines was also found in other chronic inflammatory skin diseases (i.e., atopic dermatitis), it has been proposed that an overreactive SAM system may be a common feature of chronic inflammatory Th₁-mediated (psoriasis) and Th₂-mediated (AD) inflammatory skin disease. It is well accepted that the SAM system represents a major immunoregulatory system that controls various aspects of immunity. It is suggested that a dysfunctional SAM system may increase the risk of an aberrant immune response, especially under stressful conditions in which the system is activated. In fact, a distinct redistribution of leukocyte subsets or altered cytokine production after stress has been identified in psoriatics. In these studies, it was demonstrated that psychosocial stress yielded an increased number of monocytes, CD4⁺ (Th) cells, CD8⁺ (cytotoxic T) cells, or natural killer (NK) cells, suggesting increased mobilization of these cell types in PSO sufferers. Interestingly, the immunological changes were significantly correlated with stress-induced increases of epinephrine and norepinephrine levels in these patients. The PSO-specific immunological alterations to stress may be of clinical importance. The first leukocytic infiltrate that precedes the developing psoriatic plaque consists primarily of monocytes and CD4⁺ cells. After invasion into the skin, monocytes differentiate into macrophages and can act as antigen-presenting cells. Antigen presentation, however, is necessary for the initial activation of T cells. Monocytes are further able to produce chemokines that increase T-cell trafficking and infiltration into the skin. CD4⁺ cells play a key role in the pathogenesis of PSO, and they are considered to be mainly responsible for the initiation and maintenance of the psoriatic phenotype. For example, the injection of CD4⁺ cells into prepsoriatic skin causes the phenotypic

conversion of previous symptomless skin into psoriatic skin. Activated CD4⁺ cells (and CD8⁺ cells) further produce pro-inflammatory cytokines such as IL-2, IFN- γ , and TNF- α , which are known to play a pivotal role in PSO pathogenesis. It should be noted, however, that, although the stress-induced accumulation of PSO-relevant immunocytes in the peripheral blood of psoriatics has been successfully documented, evidence of stress-induced infiltration of these cells into the (inflamed) skin has not been assessed and, thus, remains speculative. Animal data, however, indicate that acute stress may lead to a pronounced recruitment of immunocytes to the side of inflammation and, further, to a 200–300% higher infiltration of these cells into the (inflamed) skin. In this model, stress hormones seem to be involved because adrenalectomy abolished, and the injection of corticosterone and/or epinephrine enhanced, this effect.

Summary

In this article, important immunological and psychological factors related to the pathogenesis of PSO have been described. It has become clear that immunological abnormalities, such as a dysfunctional Th₁/Th₂ immune response pattern, inappropriate cytokine secretion, and keratinocyte hyperproliferation, play a key role in the onset and maintenance of the disease. On the other hand, stress has been found to aggravate the skin condition in PSO. Regarding the stress-PSO relationship, it is important to keep in mind that stress can trigger the exacerbation of the disease but, in turn, may be a consequence of a worsening of skin condition and the discomfort related to an exacerbation of the disease. This may lead to a *circulus vitiosus* that is often difficult to interrupt.

In the present overview, potential psychobiological pathways, which may be involved in the close relationship of stress and the exacerbation of psoriatic skin inflammation, have been briefly discussed. In PSO patients, distinct aberrations in important immunoregulatory neuroendocrine systems such as the HPA axis and the SAM system may lead to an immunological milieu that may render (genetically disposed) individuals more vulnerable to the development and/or exacerbation of chronic inflammation. The dysfunctional responsiveness of (neuro)endocrine stress systems such as the HPA axis and the SAM system may be of specific pathological relevance when the organism is challenged by a stressor, and an adaptive regulatory control of the immune system is required.

It is of note, however, that, although this model is built on experimental evidence, several parts of it are still speculative, awaiting validation by future

research. Trying to integrate existing facts and promising working hypotheses into a model of psycho-neuroimmunocutaneous communication and, further, to validate such a working model in future research is a challenge for the field of psychodermatology that may lead to new disease concepts and therapeutic regimens of PSO.

Starting Point

A Science of the Mind

Social Philosophy

Conflictedness of Life

Challenges

Conclusion

In the late 1890s, Sigmund Freud (1856–1939), who had been trained as a Viennese neurologist, created a new field, psychoanalysis, which was designed to understand and treat neurotic afflictions. An essential key to Freud's thinking lies in the character of the last days of the Hapsburg Empire. An unusual gulf between reality and official ideology stimulated a general intellectual revolt, a search for the actualities beneath the pious formulas of proclaimed truth. This revolt was led by those ideally placed to see the discrepancy because they had nothing to gain from accepting the official view, the educated Jews. Mor-

dant irony was an essential weapon for piercing the veil of the structure of formal beliefs. The cultural conflict between East and West that had its vortex in Vienna's cosmopolitan intellectual life and the sense that liberal culture was on the verge of being undermined, were reflected throughout Freud's mature thought.

Starting Point

Freud's starting point as a therapist was the existence of inner conflicts, which interfered with the lives of suffering patients. He proposed that symptoms be looked on as substitute satisfactions, the result of a failure to deal adequately with early childhood patterns. Freud was highlighting persistent infantilism as the ultimate source of adult neurotic problems.

Freud held that neuroses are psychologically meaningful, and he interpreted them as compromise formations between repressed impulses and censoring parts of the mind. One portion of every symptom was understood as the expression of wish fulfillment, and another side represented the mental structure that reacted against the primal wish. Initially, Freud thought that neurotic anxiety arose from sexual sources; specifically, Freud indicted dammed-up sexuality as the physical basis for neurosis.

Freud conceived sexuality so broadly as to include virtually all aspects of childish pleasure-seeking. Fantasies of sexual gratification stemming from early childhood were allegedly the source of adult neurotic dilemmas. Freud proposed that a person's emotional attitude toward his or her parents encapsulated the core problems of neurosis, and he coined the term Oedipus complex to describe a boy's first childish desires for his mother and a girl's earliest affection for her father. Freud understood that someone's emotional attitude toward a family consisted of conflicting emotions involving rivalry and guilt, not just desire. Freud believed that the most troublesome feelings stemmed from emotional problems about which the individual remains unconscious.

Freud was proposing that people have motives that can be operative without their knowing anything about them. His special viewpoint was that of a psychologist, and he sought to pierce the mysteries of memory and false recollections. Freud thought that the compromise formations in constructing our image of the past were just like those in dreaming, as well as the ones underlying neurotic symptomatology and everyday slips of the tongue or pen. He thought that the past lives on in the present and that psychoanalytic treatment consisted in the exploration of each patient's early history.

Freud was ambitious as a theorist, and his notion of neurosis became part of a full-fledged system of thought. A central implication of his approach amounted to an assault on our confidence in our ability to think rationally. Freud was insisting that people are fundamentally self-deceptive. Neurosis was a form of ignorance, and Freud saw it as his task to use the power that came from enlightenment.

A Science of the Mind

Because much as Freud's work can be understood as a critique of the capacity for self-understanding, he was superlatively rationalistic about psychoanalysis itself. He thought he had discovered a science of the mind and that he had uncovered a realm of meaning that could be verified objectively. The technique of free associations, which he relied on during treatment, was one that others could be trained to use. Once patients submitted to the analytic situation, such a commitment could be used by the analyst to promote personal autonomy. Freud was relying on a structured situation in which patients saw the analyst 6 days a week for sessions lasting 50 min each for the sake of forcing people to be free, to use the terminology of Jean-Jacques Rousseau.

One of the chief defects in Freud's approach was his unwillingness to concede the philosophical

underpinnings to his approach. He was convinced that psychoanalysis was capable of transforming thought and undermining previous moral positions, yet he fancied that he had been able to do so without importing any ethical baggage of his own inside his teachings. Yet Freud was clearly expressing a morality of his own; he once explained to a patient that the moral self was the conscious, the evil self being the unconscious. Freud qualified this distinction by maintaining that his approach emphasized not only evil wishes but the moral censorship that makes them unrecognizable. He was insistent that morality was self-evident at the same time that he himself supposedly held to a higher standard of ethics than humanity as a whole.

Because Freud wrote so much about abnormality, it might seem that he would have been obliged to discuss his picture of mental health, but whatever Freud had in mind has to be teased out of his system of thought because he remained loath to deal frontally with a concept such as normality. It is clear that he did not envisage a utopian version of personal happiness; anxiety and despair were to him inevitable parts of the human condition. Freud sought not to eradicate human conflicts but to teach how we can come to terms with them.

Social Philosophy

Although Freud claimed to be intent on steering away from speculative theorizing, he repeatedly allowed himself to become engaged in social philosophy. In each of the last three decades of his life he wrote a book centering on different aspects of the psychology of religion. He made the analogy between religion and obsessional neurosis and pointed out how often outer forms have obliterated the inner religious intention, as with any other self-defeating neurotic structure. The one social coercion Freud felt to be humanly unnecessary was religion. In "The Future of an Illusion" (1927), he stressed the inner instinctual core that strains beyond culture's reach. Freud's theories emphasized the divisions within the human mind; he was differing from the classical liberal tradition to the extent that he saw the individual not as a unit but as an opposed self. However, it is also the case that Freud proposed that there was a central portion of the self deep within humankind that had to remain in opposition to society.

Freud's enlightenment heritage led him to denounce religious belief in so bold a manner. As of 1927, Freud insisted that human helplessness was at the origin of religious conviction; people need religion because of the failure to outgrow the dependency of childhood. Religion is an illusion in the sense that

it is the product of wish fulfillment. Freud skeptically saw religion as a pack of lies, fairy tales that were a product of emotional insecurities. Because religion was based on irrational fears, its unreality may undermine the civilization it currently supports. Illusions are dangerous, no matter how comfortable. Freud ignored his earlier comments on religion, relating it to fears of death and guilt, and he concluded that superstition is intolerable. He was so intolerant of the infantile and the regressive that he had difficulty understanding their constructive functions.

Freud saw the family as the prototype for authority relationships. As he had argued that God the father was needed to allay the deepest fears, so he thought that the Oedipus complex also illuminated the social cohesion of political groups. Freud was suspicious of the masses and disdainful of the lower classes. His elitism lay behind a good deal of his social thinking. Religion always seemed to Freud a more intolerable irrationality than political authority. Politically, he was impressed by the extent of human inner instability and the craving for authority. Although Freud's whole form of therapy was aimed at liberation and independence, politically he was a pessimist.

Conflictedness of Life

In "Civilization and Its Discontents" (1930), Freud eloquently expressed his full sense of the conflictedness of life. He stressed the inevitable pervasiveness of suffering in civilized society. Although he could, as he had in "The Future of an Illusion," write like an eighteenth-century libertarian, here his sense of the inevitable cruelties of life was uppermost in the argument.

For civilization to be powerful enough to protect people from one another and from nature, it must, according to Freud, have at its disposal an equally intense energy. Throughout Freud's thought there is a sense of the limits of life, the truth behind the maxim that one cannot have one's cake and eat it too. Social unity can only be achieved on the ruins of human desires. People need the security of civilized life so deeply that they renounce the gratification of instincts in exchange for society. Freud concluded that the frustration of sexual and aggressive drives are entailed by their very character. Only if society can successfully internalize human instinctuality can civilization be maintained.

Challenges

Alfred Adler

As early as the years immediately before World War I, members of Freud's movement were challenging

some of his central points of view. Adler (1870–1937), for example, was a socialist who went on to found a school of individual psychology apart from Freud's own. Adler had a special concern with the social and environmental factors in disease and highlighted the role of compensations for early defects in his study of organ inferiority; he was proposing that, under the best circumstances, defects in a child could create a disposition toward better performance. Adler was not as exclusively concerned with infantile sexuality as Freud was but was, instead, preoccupied with ego mechanisms and aggressive drives. In contrast to Freud's own lack of interest in politics, Adler sought to improve the world through education and psychotherapy.

Carl Gustav Jung

Jung (1875–1961) led the most painful of the secessions from psychoanalysis. Even during his period of cooperation with Freud from 1906 until 1913, Jung had hesitated to extend the concept of sexuality as broadly as Freud wished, and Jung came to interpret much so-called infantile clinical phenomena as being of secondary rather than causal importance; current difficulties, he held, could reactivate past conflicts. Jung insisted that the past can be used defensively to evade the present, a clinical point that later commanded widespread agreement. Less rationalistic and suspicious of the unconscious than Freud, Jung began to formulate his own views on the compensatory functions of symptoms. No better critique of Freud's excessive rationalism can be found than in Jung's collected works. He proposed that symptoms are always justified and serve a purpose. He was also interested in other stages of the life cycle than the oedipal one. It is still not widely known how early Jung emphasized the central importance of establishing a personal rapport between the patient and analyst if therapy is to be successful.

Further Development

The full-scale development of ego psychology was one of the main developments of psychoanalytic theory since the late 1930s, and it silently incorporated most of the central objections that people such as Adler and Jung had had to Freud's original formulations.

Following Freud's death in 1939, more attempts were made to correct the negativism that had been built into his earlier work. Freud's whole system was designed to explain motivation when a person is in conflict and the ego has relatively failed at its integrative task. As a therapist, Freud was preoccupied with pulling problems apart and tearing fixations asunder, on the assumption that the patient's

ego would be able to put the pieces back together again. For Freud, analysis was automatically synthesis; constructive processes had originally been taken for granted by him.

Freud was a master at understanding the main means of self-deception, but he ignored many processes of self-healing. Therefore, a main trend after his death was to correct this imbalance and to focus on the ego as an agency integrating inner needs and outer realities. The ego has a unifying function, ensuring coherent behavior and conduct. The job of the ego is not just the negative one of avoiding anxiety but also the positive one of maintaining effective performance. The ego's defenses may be adaptive as well as maladaptive. Adaptation is itself bedeviled by anxieties and guilts, but the ego's strength is not measured by the earlier psychoanalytic standard of what in a personality is denied or cut off but, rather, by all the extremes that an individual's ego is able to unify.

At the same time, psychology shifted from the more traditional concern with the defensive ego to the problems of growth and adaptation; it looked for the collective sources of ego development. For instance, there can be a need for a sense of identity to be confirmed by social institutions, as Erik H. Erikson (1902–1994) pointed out; and here organized religion and ritual can play a positive role. Cultural institutions not only can play a constructive role, but they help account for the variety of psychological patterns that can be found in different societies.

In his respect for the dignity of his patients, which made his innovations possible, and in his conviction that despite appearances all people are psychologically one, as well as in his individualistic goals, Freud was a great heir of the enlightenment. He was among those who are ever demanding more freedom. At the same time, however, in the development of psychoanalysis the open-ended quality of liberalism led to a revision of some of its most cherished premises; Freud represents an aspect of liberalism's self-examination. In Freud's quest for an understanding of human feelings, he transcended liberalism and joined hands with thinkers usually associated with traditions alien to it. He demonstrated the degree to which the child lives on within the adult and the way psychological uncertainties can prevent people from ruling themselves.

The humanistically oriented revisionists of Freud's views, for example, Erich Fromm (1900–1980), were trying to inject genuine humanitarianism into a psychoanalytic worldview that appeared with Freud to have ended in therapeutic despair and ethical nihilism. In correspondence and conversation, Freud acknowledged that health was only one value among others and that it could not exhaust morality

as a whole. If he was wary about this whole subject of normality, it was because he realized what kind of quagmire he was in danger of entering. He touched on the subject of normalcy only on the rarest occasions. Freud typically took for granted that the people he liked best to work with were creative and self-disciplined.

Freud feared that the most original and disturbing aspects of his ideas would be destroyed by the widespread popular acceptance of his ideas in North America, yet it is questionable whether he did enough to prevent precisely this outcome. By not providing more hints about normality and not owning up publicly to the wide variety of psychological solutions he found both therapeutically tolerable and humanly desirable, Freud contributed to what he most sought to prevent. He had set out to transform Western values; he was eager to go beyond accepted good and evil. When he assaulted the maxim "love thy neighbor as thyself" as both unrealistic and undesirable, he was explicitly trying to overturn Christian ethics.

Conclusion

It is logically impossible to talk about neurosis without at the same time implying a standard of maturity as well, and yet despite how powerful psychology can be in outlining human defects and weaknesses, it has not been nearly as successful in coming to terms with the positive side of human strength and coherence. In the end, the issue of the significance of normality and its relationship to nihilism has to be left an open question. Freud's psychology did contribute to our understanding of what it can mean to be human. However, it is impossible to attempt to spell out in a definitive way the ideological implications of psychoanalysis. The writers who have been influenced by Freud constitute a wide range of people, from the most radical to some of the most conservative.

It was an old analyst and loyal disciple of Freud, Helen Deutsch (1884–1982), who had the most appropriately philosophical attitude toward the perplexing issue of normality. In her earlier years, when she was one of the most prominent teachers in the history of psychoanalysis, she made it a practice in the course of interviewing prospective analysts for acceptance into training to ask what they thought a normal person would be like. It is, of course, an ultimately unanswerable conundrum and yet one that civilized people are obliged to raise repeatedly. Like all genuine questions in social philosophy, the problem of normality can never be solved; it has to remain a real issue to the extent that we find it intolerable to contemplate a universe lacking in moral values.

The enhanced and progressive sensitivity of an organism to stress given repeated exposure to stressors.

Historical and General Considerations

Conceptual Progress

Methodological Considerations and Recent Developments

Glossary

Catecholamines Neurotransmitters, including epinephrine, norepinephrine, and dopamine, that promote sympathetic nervous system activity. They may be released in substantial quantities during stressful times.

Corticosteroids Complex chemical compounds produced in the outer layer of the adrenal gland, which include both mineralocorticoids and glucocorticoids. Mineralocorticoids maintain salt and fluid balance in the body, while glucocorticoids have metabolic and anti-inflammatory effects and are important mediators of the stress response.

Neuroendocrine Relating to the nervous and endocrine system, which produces endocrine

Historical and General Considerations**Historical Matters**

It is frequently assumed that psychological stressors are a concern of especially modern origins, or at least that they have become more prominent with recent advances in society and technology. It is also commonly assumed that with the accelerating progress of civilization, more and more people are afflicted with mental and physical disorders. Historical accounts, however, suggest that such ideas about stressors, civilization, and disease have been common for quite some time. Sir Clifford Albutt (1895: 217) expressed such sentiments quite clearly well over 100 years ago:

To turn now . . . to nervous disability, to hysteria . . . to the frightfulness, the melancholy, the unrest due to living at a high pressure, the world of the railway, the pelting of telegrams, the strife of business . . . surely, at any rate, these maladies or the causes of these maladies are more rife than they were in the days of our fathers?

The tendency to view life in stressful terms may be even more basic to human cognition than is readily

apparent. The Greek myth of Sisyphus is enlightening in this regard. The perpetual work of pushing a boulder up a mountain – only to have gravity bring it back down after each and every effort – captures some of the qualities and characteristics linked to modern views of psychological stressors. Perhaps there is something fundamental about the human condition and psyche that fosters a perception of the world as a place rife with unrelenting demands that can never be fully met, resulting in subjective states of fatigue and distress and eventually leading to ill health. Each era may bring its unique colorations to such perceptions and its own attributions regarding their origins.

It is against this psychological backdrop of belief and possible bias in thinking that modern work on psychological stressors must be examined. Psychological stressors and related concepts have been popular explanatory constructs throughout recent, and perhaps not so recent, history. As a result of their subjective allure and apparent explanatory power, these ideas have often been loosely formulated. Owing to conceptual fuzziness and ambiguity, not only has progress in science been slowed, but nonscientific issues, ideas, and biases have been permitted to masquerade as scientific truths.

The concept of psychological stressors is rich with possibilities for shedding light on important matters in adaptation, dysfunction, and disease. The concept is paralleled, though, by the potential pitfalls that accompany its intuitive appeal. The challenge is to translate the fertile ideas about psychological stressors into more precise concepts, definitions, and operational procedures. With more sound definitional and methodological procedures in place, the utility of stress concepts for understanding adaptation and maladaptation, mental and physical disorder and disease, will be better understood.

Early Ideas and Research

A broad foundation for understanding the organism's reactions to challenging environmental circumstances was laid down by Claude Bernard and Charles Darwin during the nineteenth century. Each of these two influential individuals in his own way touched on issues deriving from the tension resulting from ongoing adaptation to changing and challenging environmental circumstances. Yet it was not until the early to mid-twentieth century that such generality and complexity began to be translated into more specific terminology and technology. These efforts can be traced to at least three different lines of thought and research.

The early work of Walter Cannon dealt with ideas about common emotions and their physiological consequences, particularly with respect to the body's maintenance of homeostasis. This line of study was

complemented shortly thereafter by the animal laboratory studies of Hans Selye, wherein acute and severe stressors were systematically investigated. It was in Selye's work that the concept of stress most forcefully emerged. Stress was defined as "the nonspecific response of the body to any demand" (Selye, 1976: 74). Stressors, in turn, were defined as "that which produces stress" (Selye, 1976: 78). Finally, from another vantage point, Adolph Meyer popularized the life chart methodology. This approach emphasized the importance of the dynamic interplay between biological, psychological, and social factors, such that important events within the person's biography became foci of attention for studying health and disease. Collectively, these activities, and the multiple lines of research they generated, served to initiate specific awareness of, and interest in, psychological stressors.

Arising outside of the more purposeful activities of science was another influential development that contributed to the emerging idea that psychological stressors cause both mental and physical disorders. Prior to World War II, psychopathology was commonly attributed to genetic factors or acquired biological propensities; so-called normal people devoid of such taints were thought to be largely invulnerable to mental illness. The experiences during and after World War II dramatically shifted thinking in medical and psychiatric circles to incorporate the idea that severe stress could precipitate breakdown in a previously healthy individual. Once this conceptual shift began, it underscored the multiplicity of health consequences that could be caused by severe stressors. It also opened the door for enlarging conceptual perspectives on psychological stressors by considering how less severe, yet still noxious, aspects of the social and physical environment could contribute to, or precipitate, pathology.

Conceptual Progress

Upon the foundations of stress research and theory laid down by Selye, Cannon, and Meyer, along with the influences of experiences of World War II, modern inquiry into the effects of psychological stressors became a topic of increasing interest and, eventually, of extensive empirical inquiry. Two general themes may be discerned that have underpinned advances in theory: (1) characteristics of psychological stressors and (2) individual differences in response to psychological stressors.

Stressor Characteristics

Despite general agreement about the importance of psychological stressors for health and well-being,

determining exactly what it is about stressful circumstances that is deleterious has proven challenging. An initial question of considerable theoretical importance involved the basic nature of psychological stressors: are they best viewed in a unitary manner as nonspecific demands on the organism (as postulated by Selye), or are psychological stressors more effectively viewed as a class of conditions harboring specific component characteristics of importance? Investigators from two traditions – animal and human research – have addressed this issue, with parallel and sometimes intersecting developments. Although considerable progress has been made, the general topic of elaborating stressor characteristics remains one of central importance in current thinking on psychological stressors.

Animal Laboratory Research

A great deal of work in the 1960s and 1970s was performed to determine whether specific psychological characteristics of stressors possess qualitatively distinct implications for the organism. Initially this work revealed how particular features associated with the environmental stressors might be important for predicting adverse outcomes (as opposed to the more psychologically neutral notion proposed by Selye of general or nonspecific adaptive demands). Such research went on to probe the types of psychological stressors and their effects. It became of central interest to understand in a more differentiated way the effects of diverse psychological stressors.

Animal laboratory studies adopted ingenious designs to differentiate psychological components associated with environmental stressors, with the findings from these studies demonstrating that distinctive psychological characteristics were responsible for many immediate behavioral or physiological responses. For example, specific psychological characteristics of stressors, such as undesirability or controllability, were particularly pertinent for the development of various disorders. It became clear, too, that other characteristics of stressors were important. For example, different parameters of shock administration (acute, intermittent, or chronic) produced different physiological effects in animals. Further, such differences might increase, decrease, or not influence the development of particular diseases. Finally, psychological stressors not only could influence immediate psychobiological functioning, but also could have long-term ramifications through permanent alteration of the organism.

As the importance of specificity of stressor characteristics became more apparent and accepted, questions about the specificity of stress responses also arose. What were the implications of specific stressor

characteristics for different facets of psychological and physiological functioning? Such theoretical developments greatly extended the framework for inquiry, requiring attention to multiple characteristics of stressors in relation to multiple psychological and biological processes and outcomes. Relatively simple, singular response indices (e.g., corticosteroids, catecholamines) were replaced by patterns of behavioral and biological effects or profiles of neuroendocrine responses. More recently, other levels of conceptualization have been proposed. For example, psychological stressors may promote fundamental disruptions in oscillatory regulation of basic biological functions or reversions to earlier modes of functioning.

Overall, research on psychological stressors from animal research has moved beyond unidimensional and linear concepts of stressors and their effects. More recent thinking has adopted a larger framework for understanding the diverse characteristics of stressors that influence particular and varied response systems of the organism. The response systems of interest have expanded from single systems to patterns or profiles of response across multiple indices.

Human Experimental and Field Studies

Investigators of psychological stressors in humans also conducted innovative and insightful studies, both in the laboratory and in the field. Early work tended to focus on the aversive subjective attributes, particularly perception or appraisal, of psychological stressors as evaluated in an experimental setting. Yet at about this same time research on stressful life events began. It is in this area of stress research that activity on psychological stressors perhaps reached its pinnacle, in terms of both productivity and popular interest.

Extrapolating from animal laboratory studies on the one hand, and integrating with Meyer's life chart procedures on the other, Thomas Holmes and Richard Rahe first formulated the idea that distinctive changes in one's life circumstances – specific and documentable life events – could be defined and assessed in an objective manner. The work was initially based on case histories of some 5000 tuberculosis patients, from which they derived a list of 43 life events "empirically observed to occur just prior to the time of onset of disease, including, for example, marriage, trouble with the boss, jail term, death of spouse, change in sleeping habits, retirement, death in the family, and vacation" (Holmes, 1978: 46). The Schedule of Recent Experiences (SRE) was developed and published, and by 1978 more than 1000 publications had utilized this convenient method for

probing a vast range of questions pertaining to stress and illness.

The common feature associated with these disparate life changes – the stressor characteristic of primary concern – was thought to be the degree of social readjustment entailed by the event: “The relative importance of each item is determined not by the item’s desirability, by the emotions associated with the item, nor by the meaning of the item for the individual; it is the amount of change that we are studying and the relationship of the amount of change to the onset of illness” (Holmes, 1978: 47). This viewpoint is consonant with Selye’s ideas about stressors and stress. Hence, the psychologically neutral notion of the readjustment required of life changes was conceptualized as the characteristic responsible vulnerability to a wide variety of psychological and physical maladies.

Much as the emphasis in animal laboratory studies shifted from psychological neutral concepts of any demand, viewpoints within the stressful life events literature began to shift away from the concept of readjustment and toward emphasizing the undesirable characteristics of events. Human studies of life events consequently began to focus on the particular characteristics of psychological stressors and their potentially unique effects. The principle of specificity also was extended from the characteristics of stressors to the specific consequences of such experiences, elaborating theory about the importance of specific psychological stressors for specific responses and eventually for specific types of disorder or disease. A vast literature on this topic has appeared over the past two decades, with diverse conceptualizations of psychological stressors and myriad methods designed to measure them.

The issue of desirability of events, however, along with the more general issue involving stressor characteristics, brought into focus another important subject in the study of psychological stressors: individual differences. What might be viewed or experienced as undesirable by one person could be viewed or experienced as desirable by another. As discussed next, a variety of considerations are invoked to explain variability in effects and outcomes in relation to psychological stressors.

Individual Differences

Despite progress in conceptualizing the component characteristics of psychological stressors, and despite progress in prediction afforded by such work, considerable variability in response to psychological stressors occurs. Even under the most dire of stressful conditions, all animals or individuals do not

necessarily break down. Although a refined understanding of stressor characteristics still may account for some variability in outcomes, other factors may be useful to effectively model effects of psychological stressors. Progress in understanding this issue has again come from both the basic laboratory and human studies of psychological stressors.

Animal Laboratory Research

Although there were characteristic features of physiological responses to the stressors employed in the early paradigm adopted by Selye, not all animals responded to stress in an identical manner. Further, individual differences in response were even more pronounced when the less severe types of stressors were used.

Such variables as prior experience, availability of coping responses, and other aspects of the social and experimental context were found to moderate the influence of psychological stressors. For example, when rats are exposed to electric shock, animals that cannot predict shock occurrence (via warning tones) develop a sixfold increase in gastric ulceration compared to their yoked counterparts (who receive the warning tones). Work along these lines demonstrated the delicate and often subtle interplay among stressor, social context, and resources available to the organism in determining response outcomes. These lines of study, too, suggested that individual differences in susceptibility to psychological stress could be viewed within a developmental perspective in terms of stress sensitization. Laboratory animals repeatedly exposed to severe psychological stressors can become neurobiologically sensitized to the stressors, such that relatively minor degrees of stress eventually acquire the capability of triggering pathogenic responses.

Human Life Stress Research

The importance of individual differences was perhaps more apparent in studies of human life stress and its consequences. A consistent criticism of life events research was the relatively weak association between psychological stressors and disorder. It was assumed that other considerations moderated stress effects, and the elucidation of such factors would increase the predictive capability of disorder following stressful events. Again, there were a number of factors that were believed to moderate the impact of psychological stressors, ranging from environmental factors such as social support to more individual factors such as prior experience and coping. Developmental considerations have also been important in recent theorizing about individual differences in responsivity to

psychological stressors, with the idea that prior exposure to severe psychological stressors renders the individual more susceptible to increasingly lower levels of psychological stress.

A major arena for understanding individual differences in stress susceptibility has been perception. The early and elegant laboratory studies of human stress had indicated the importance of such individual differences in perception, or appraisal, of stressors, and such thinking was readily incorporated into theory and method. Studies of life events, for example, used subjective weights of events experienced by the study participants. Once this avenue of inquiry was opened, it also brought to the forefront a variety of influences on perception, along with other factors that might influence stress responsivity. Thus, research began to focus not only on appraisal of stressors, but also on coping, social support, personality, and other considerations that in theory could moderate the effects of psychological stressors.

As research progressed along these lines, it became clear that making some of these distinctions was easier to do in theory than in method. For example, while it made good sense theoretically to consider an individual's subjective perception of psychological stressors, it was more difficult to employ such information in a scientifically sound manner. When it came to operationalization, serious problems became apparent. For example, owing to depression-based perceptual biases, a depressed person might have a skewed perception of events and rate them as particularly negative (irrespective of the objectively stressful qualities *per se*). Generally, such concerns raised an important paradox for investigations of psychological stressors. Namely, although a large part of the desired knowledge pertained to the individual's idiosyncratic appraisal of psychological stressors, methodological concerns cautioned against direct assessment of such information. Instead, alternative approaches were developed to avoid the pitfalls of using subjective reports in research on psychological stressors, as well as to avoid other problems with these methods that eventually came to light.

Methodological Considerations and Recent Developments

While concepts and methods often intertwine and, united, nurture progress, at times one or the other component may unduly influence development (for good or for bad). This situation appears applicable to research on psychological stressors, in which the methods adopted in animal laboratory research have constrained theory and methods adopted in human

life stress research have misled theory on psychological stressors.

Animal Laboratory Research

The original work of Selye typically employed situations that were overpowering or unavoidable for the animal. Such conditions did not permit an evaluation of behavioral responses or other moderating influences that could influence an animal's adaptation to stressors. Further, it was realized that this methodological paradigm was not informative about psychological stressors that might be of greater ecological and evolutionary relevance (i.e., more typical with respect to the animal's natural environment and evolutionary history). Thus, such an approach readily masked the implications of less severe psychological stressors on physiology and behavior, which in turn might represent a more fertile area of inquiry into stressor effects. Finally, the nature of the stressor employed in the early stress laboratory studies also contributed to the aforementioned difficulty in differentiating physical from psychological effects, which inhibited progress in the arena of conceptual development.

Overall, the range of psychological stressors was constrained by the methods adopted. Theory, in turn, was constrained to account for the consequences of stressors under such restricted and relatively unnatural stressor conditions. More recent research has benefited from methods that encourage assessment of diverse characteristics of psychological stressors and their severities and incorporate the assessment of a wide variety of behavioral and biological response possibilities. Current perspectives based on these broader methodological approaches suggest that the organism's responses are often exquisitely specific nuances of stressors encountered.

Human Studies of Stressful Life Events

The bulk of empirical work on human life stress has been based on self-report checklist methods. The prototype of this approach is the SRE, the instrument that catalyzed research in this area. The popularity of the SRE was likely due to the combination of the intuitive appeal of the stress concept, the apparent objectivity of the method, and the overall impression of scientific legitimacy.

The methodological paradigm launched by the SRE, however, embodied several problems. It became clear that subjects did not report life events in a reliable manner over time and that investigators did not adequately control for the directionality of effects in research designs (e.g., being depressed initially could bring about life events such as trouble at work,

difficulties with spouse, and so on). Indeed, many of the initial items on the SRE were direct indicators of disorder or illness. For example, some of the key criteria for defining clinical depression were represented in the original SRE (e.g., major change in eating habits, major change in sleeping habits). If measures of life events were directly confounded with the presence of disorder or were contaminated by the effects of pre- or coexisting disorder, then clearly general theory about psychological stressors, as well as theory about the characteristics of psychological stressors, rested on flawed information.

In response to these methodological concerns, other investigators designed semistructured interview protocols and developed explicit guidelines, decision rules, and operational criteria for defining and rating life events. These developments further highlighted serious problems with self-report checklist methods. For example, there was too much subjective leeway permitted in defining what constitutes an event with self-report procedures, resulting in considerable variability of content within ostensibly uniform categories of events. In order to have a more firm methodological foundation, the more elaborate and extensive interview and rater-based procedures were employed, which helped to standardize measurement across individuals.

In general, such interview and rater-based approaches have been found to enhance the reliability of life event assessments and to provide stronger predictions of particular kinds of disorders following the occurrence of psychological stressors. Procedures such as these also provide a solid foundation upon which to build in terms of developing taxonomies of psychological stressors and their effects. Although such approaches are more time- and labor-intensive to implement, they represent the current-day gold standard for assessing psychological stressors.

Human Studies Employing Other Measures of Psychological Stressors

There have been other methods in which psychological stressors have been defined and studied. None of these approaches has received the degree of attention devoted to the work on life events, yet each may have useful properties for the study of psychological stressors. Two lines of investigation are noteworthy.

Many investigations have targeted people who experience a specific life event and compared these individuals with controls who do not experience the event. For example, individuals who become unemployed are compared to individuals who do not experience this event in relation to a variety of psychological and physical processes and outcomes. Such work is useful for examining a potentially

more homogenous process with more readily identifiable outcomes. On the other hand, such studies may oversimplify the psychological stressors associated with an event and not specifically articulate the different components within the general event that are most pernicious for health and well-being. For example, the effects can be partitioned into a variety of stressful themes that, although often intercorrelated, may not have uniform effects. Thus, although people who become unemployed in general may experience a loss of self-esteem, loss of income, loss of daily schedule, and so on, each particular situation may pull more or less for heightened responses along these different dimensions. Work sensitive to such variability in the component characteristics will be most useful for research on psychological stressors.

Finally, there also have been efforts to measure psychological stressors through questionnaire or diary methods, inquiring about minor but common daily events, chronic conditions, appraisal processes, and other indicators or correlates of psychological stressors. A promising recent avenue of research involves ecological momentary assessment, where subjects can be prompted throughout the day to respond to queries about their circumstances and psychological states. Such procedures help minimize problems with standard retrospective methods.

In closing, it is appropriate to return to the concerns and caveat with which the article began. The specter of possible biases in the measurement of psychological stressors must be consistently borne in mind, and methods employed must be rigorously attentive to such concerns, to provide a solid empirical foundation upon which theory and research can build for this important area of investigation.

Immune System

Relationships between the Nervous System and the Immune System

Functional Consequences of Relationships between the Nervous System and the Immune System

Immune Influences on Brain Functions

Implications for Psychosomatics

Glossary

<i>Cytokines</i>	Secreted regulatory proteins in response to external insults that control the survival, growth, differentiation, and effector function of tissue cells.
<i>Immune system</i>	A complex network of specialized cells and organs (lymphoid organs) that distinguishes between self and nonself and defends the body against infections from agents such as bacteria, viruses, fungi, and parasites.

Immune System

Immunology deals with understanding how the body distinguishes between what is self and what is non-self. The classic hallmark of the immune system is its ability to recognize and kill foreign substances and at

the same time recognize but not destroy normal host tissues. To protect against potentially pathogenic microorganisms that are foreign to the body (antigens), the host uses white blood cells, or leukocytes, that originate from precursors in the bone marrow. These cells circulate through the blood and lymph system or, for some of them, are fixed in specific tissues. Innate immunity represents the first line of defense against antigens and involves phagocytic cells that are mononuclear (e.g., macrophages) and polymorphonuclear (e.g., neutrophils). These cells capture microbes and digest them, and the mononuclear macrophages also present antigen fragments to lymphocytes. Lymphocytes have highly diverse specific receptors, which allow them to recognize antigens. Adaptive immunity is based on the proliferation and differentiation of antigen-specific lymphocytes into effector cells. The T lymphocytes, so designated because they differentiate and mature in the thymus gland before traveling to the spleen and lymph nodes, are the first of the lymphocytes to be activated. Following contact with antigen-presenting cells such as macrophages, lymphocytes proliferate and destroy the infected cells, in which case they are called cytotoxic T lymphocytes, or they help other lymphocytes to intervene.

There are many different subclasses of T cells that can be distinguished from each other by specialized cell surface molecules. For instance, cytotoxic T lymphocytes are called CD8 positive T cells because they express a glycoprotein known as CD8. CD4 positive T cells, which are markedly depressed in patients suffering from acquired immunodeficiency syndrome, are essential for the activation of macrophages and

B lymphocytes. Other lymphoid cells, called natural killer (NK) cells, are specialized in the recognition of tumor cells. B lymphocytes, so designated because they develop in the bone marrow of adults, differentiate into plasma cells that produce antibodies when they bind antigen and are co-stimulated by a subset of T cells. Antibodies, also called immunoglobulins (Ig), are soluble molecules that attach specifically to antigens, making their destruction possible through a series of complex reactions involving complement molecules. An immune response results in the generation of an increased number of differentiated memory lymphocytes that, upon re-exposure to the same antigen, generates more rapid and effective response. Some antigens induce the production of specialized antibodies, known as immunoglobulin E (IgE), that bind to the surface of mast cells. Recognition of an antigen or allergen by IgE attached in this manner induces the release of various mediators (e.g., histamine and serotonin) that are contained in the secretory granules of mast cells and are responsible for an allergic reaction.

The various cells that are involved in immune reactions communicate with each other by cell-to-cell contact via specialized adhesion molecules and by soluble mediators known as cytokines or interleukins. These two forms of cell-to-cell communication are essential for the initiation and regulation of the host response to infection. Each category of immune cells produces characteristic cytokines. Activated monocytes and macrophages produce the proinflammatory cytokines that are necessary for the development and regulation of the inflammatory response and include interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α). Two subsets of CD4 positive T cells, or T helper (Th) cells, can be distinguished on the basis of their profile of cytokine secretion and the type of immune response they promote. Th 1 cells secrete IL-2, interferon- γ (IFN- γ), and TNF- α , whereas Th2 cells release IL-4, IL-6, and IL-10. Th1 cells are major players in delayed-type hypersensitivity and proinflammatory responses, whereas Th2 cells induce B cell growth and differentiation.

Relationships between the Nervous System and the Immune System

Although the immune system has long been viewed as a self-regulated system, there is now a wealth of evidence in favor of the existence of intricate anatomical and functional relationships within the nervous system. In particular, branches of the autonomic nervous system innervate the spleen and lymph nodes. Immune cells have functional membrane receptors for both classical neurotransmitters and neuropeptides.

This is important because it implies that immune cells proliferate and differentiate in a microenvironment, the composition of which is dependent on the activity of the sympathetic nervous system. In addition, leukocytes themselves are able to produce and release many peptides that have been identified initially in the neuroendocrine and nervous system, such as pro-opiomelanocortin, corticotropin-releasing hormone, growth hormone, and insulin-like growth factors. Conversely, microglial cells, which are the equivalent of macrophages within the central nervous system, are able to synthesize and release proinflammatory cytokines such as IL-1 and TNF- α that are involved in the regulation of the inflammatory response at the periphery, and brain cells also express receptors for these and other cytokines.

Functional Consequences of Relationships between the Nervous System and the Immune System

The commonality of messengers and receptors between the immune system and the nervous system provides new vistas into the old notion that psychological factors can influence the development and evolution of somatic diseases. Objective studies on the influence of psychosocial factors and specific emotional states on immune responses are now possible thanks to the development of quantitative methods for assessing changes in immunity in animals and human subjects. In animal studies, exposure to a variety of stressors, including painful electric shocks, physical restraint, social separation, and the odor of another animal that is stressed, can depress NK cell activity and T and B lymphocyte proliferating response to nonspecific mitogens. Psychological aspects of stressors, particularly the subject's ability to predict and control their occurrence, are more important than their severity, frequency of occurrence, and duration. The effects of stress on immunity depend on the immune response under consideration, and a given stressor can either suppress or enhance different immune responses in the same individual. For example, mice that were exposed for 24 h to the odor of another stressed mouse display a decrease in IL-2 production by splenocytes stimulated with a T cell mitogen, a reduction in NK cell activity, and an increase in IgM and IgG antibody titers against a T cell-dependent antigen. These apparently disparate results can be interpreted as an effect of stress on the Th1/Th2 balance, in the form of activation of Th2 cells and downregulation of Th1 cells. Human studies show that immune functions can be altered by various experimental procedures, such as emotion induction under controlled laboratory conditions

and naturally occurring life events, such as academic examination, difficulties in marital life, and intractable diseases (e.g., cancer, early dementia) affecting the spouse. Major depression is accompanied by alterations in the distribution of T cell subsets and by declines in nonspecific measures of immunity such as NK cell activity and mitogen-induced lymphocyte proliferation. However, there are also signs of immune activation, in the form of increased numbers of leukocytes, neutrophils, and activated T lymphocytes, and an increased production of Th1-like cytokines.

Pathways involved in the mediation of the effects of stress on immunity can be identified by interfering with the activity of the autonomic nervous system and endocrine glands that are known to be involved in neuro-immune interactions. Experimental studies have made it clear that glucocorticoids are not the sole mediator of the effects of stress on immunity. Activation of the autonomic nervous system plays an important role, probably by altering the molecular composition of the microenvironment in which lymphocytes proliferate and differentiate.

The possible consequences of stress-induced immune alterations on the host resistance to infectious disease or the progression of tumor cells are not easy to assess. The relationships between stress and disease are already extraordinarily complex, and in most cases, the importance of the association between stress and illness behavior (symptom awareness and use of health services) is blurring the picture. It is now obvious that there is no global answer to this issue. In each case, a slow and cautious approach, in which the whole set of relationships among a stressor, a specific pathway, immunity, and disease is examined systemically, is more likely to yield valid answers.

Immune Influences on Brain Functions

Infection with foreign agents, in the form of infectious microorganisms or nonreplicating antigens, has long been known to cause a classical stress response, involving activation of the hypothalamic-pituitary-adrenocortical (HPA) axis and increases in catecholamine turnover in the brain and periphery. It is now apparent that these neuroendocrine and neurochemical changes form part of a larger, physiological regulatory system that modulates functional activities of lymphocytes and phagocytes. Molecules that signal the brain that an immune event has been initiated in the periphery have been identified. They are represented by proinflammatory cytokines, such as IL-1 and TNF- α , that are synthesized and released by

activated macrophages and monocytes during the course of an infection. These peripherally released cytokines act on the brain by two pathways: a neural pathway that involves sensory fibers innervating the bodily site of infection and a humoral pathway that involves blood-borne cytokines and activated circulating immune cells. In the first case, the transmission of the immune message to the brain is direct, whereas in the second case, it needs to be relayed by specialized parts of the brain that have a deficient blood-brain barrier and are known as circumventricular organs because of their anatomical location around the brain ventricles. In response to these peripheral signals, glial cells produce proinflammatory cytokines that, by acting on neural target cells, activate the HPA axis, resulting in an increase in circulating glucocorticoids. This response is important for the regulation of the immune response, as glucocorticoids feed back on activated immune cells and attenuate the synthesis of proinflammatory cytokines. Glucocorticoids also act on target cells of proinflammatory cytokines to block the transcription effects of these cytokines. The lack of a glucocorticoid response to an inflammatory stimulus is responsible for development of the disease in experimental models of autoimmune diseases in animals, whether the disease is induced by the administration of specific antigens (e.g., adjuvant-induced arthritis and experimental allergic encephalomyelitis in the Lewis rat) or develops spontaneously (e.g., autoimmune thyroiditis in the obese chicken). In addition to their potent effects on the HPA axis, proinflammatory cytokines also induce fever and nonspecific behavioral responses to infection, such as malaise, pain, fatigue, sleepiness, anorexia, apathy, social withdrawal, irritability, and cognitive deficits. The development and duration of these physiological and behavioral alterations are regulated by molecules called cryogens that oppose the effects of proinflammatory cytokines. Cryogens include neuropeptides, such as vasopressin and α -melanotropin, and anti-inflammatory cytokines, such as the IL-1 receptor antagonist (IL-1RA) and IL-10.

The profound influences of cytokines on brain functions offer insights into understanding why patients afflicted with cancer or hepatitis C experience flu-like symptoms and develop acute psychotic or depressive episodes when injected with recombinant cytokines. Furthermore, many chronic inflammatory conditions have been demonstrated to be also associated with priming of the brain cytokine compartment, so that a local or a systemic immune challenge can precipitate the occurrence of cognitive alterations and mood disorders. This is particularly the case in

aged persons, obese subjects, and patients suffering from atherosclerosis. It could explain the higher prevalence of mood and mild cognitive disorders that is associated with such conditions. In addition to peripheral influences on brain cytokines, it is important to note that proinflammatory cytokines are also induced in the brain by infiltrating blood cells after a brain trauma, a stroke, or a local immune mediated inflammatory response that compromises the blood-brain barrier. The proinflammatory cytokines that are produced in these conditions play a pivotal role in the pathogenesis of the corresponding neurological disease. They induce proliferation of astrocytes and neurodegeneration via necrotic and apoptotic routes, and they are also responsible for the psychopathological and neurological alterations accompanying the disease (e.g., AIDS-related dementia).

Implications for Psychosomatics

Demonstration of the potent behavioral and psychological effects of cytokines has important implications for understanding the relationships between stress and disease. It is no longer tenable to go only one way and claim that life events interacting with personality traits, mood, and psychological variables play a causal role in the pathogenesis of immune-related diseases because of their autonomic and hormonal concomitants. Emotional dispositions and psychological characteristics can be the result of alterations in brain functions caused by still undetectable alterations in immune functions. In the case of cancer, for example, feelings of helplessness and hopelessness that have been related repeatedly to the onset and progression of a tumor may be secondary to central effects of soluble products released by immune cells of the host or even tumor cells during the early stage of the disease, when cancer is still not clinically detectable. The inflammatory response to cancer treatments, especially radiotherapy; can have similar consequences on brain functions.

Research on the effects of psychosocial factors on the onset and progression of diseases ranging from AIDS to allergies and musculoskeletal disorders is now taking a new turn. In an organism in which physiological systems are interconnected by reciprocal regulatory systems, a dysfunction in one system is likely to affect the functioning of other systems. In addition, the dysfunction can be at the level of the regulatory process itself rather than within one of the regulated organs. The immune system has long been represented as a self-regulated system that is relatively insensitive to the host's physiological turmoil. It is now clear that this view is inappropriate, and that reciprocal connections between the brain and the immune system play an important part in the coordinated response to infection and inflammation. The challenge now is to understand how such regulatory, homeostatic mechanisms can be compromised and lead to disease.

Implications for Intervention

Glossary

<i>Self-efficacy</i>	Personal beliefs about one's ability to master challenges.
<i>Self-esteem</i>	Firm feelings and beliefs about one's own worth as a person (influenced strongly by experience on how significant others react toward one's self early in life).
<i>Social anomie</i>	Lack of social rules and orientations in a social group, often associated with feelings of anxiety or helplessness.
<i>Social capital</i>	Patterns of cooperative social exchange in neighborhood and community life characterized by mutual commitment and trust.
<i>Social role</i>	Set of expectations or norms (duties, options) directed toward people who hold important social positions (e.g., family role, work role).
<i>Type A behavior</i>	Complex of behaviors and emotions defined by excessive striving, competitiveness, hostility, and impatience.

General Background

In evolutionary terms, the development of the human brain, particularly its neocortical structures, has critically advanced the species' capacity to cope with environmental challenges and threats. As a consequence, inherited biobehavioral patterns of response to threats to the integrity, survival, and reproduction of the organism have become more variable and complex compared to those of the nonhuman primates. Increasingly, these patterns of response depend on the appraisal of stimulus properties and available opportunities for successful agency and are modulated by prior experience, learned skills, and interpersonal support. This may hold true for responses to natural and man-made disasters and for chronically demanding

socioenvironmental conditions. However, in all these instances, a person's sense of the control over the challenge and over his or her actions in dealing with it must be considered a crucial variable that triggers the quality and intensity of stressful experience. Stressful experience is defined as the experience of a mismatch between the demands put on an individual in a challenging situation and his or her ability to meet the situation with adequate responses. At the level of emotional reactions, this mismatch is likely to elicit feelings of anxiety, irritation, anger, disappointment, or even helplessness and despair. These emotions are often paralleled by sustained neuronal and neuroendocrine activation due to the existence of powerful neuronal circuits that link neocortical information processing with mesolimbic and brain stem activity.

Humans are particularly vulnerable to the distress-enhancing effects of socioenvironmental challenges and threats because the preservation of a person's self relies so heavily on his or her social surrounding. In human infancy, attachment behavior, which develops through reciprocal exchange with a caregiver, is essential for survival and normal psychological functioning. Later in childhood and adolescence, a person's social identity emerges from recurrent exchange with significant others. Moreover, in adult life, core social roles, such as the work role and the family and marital role, serve to link the individual person with a structured, goal-oriented social environment. Thus, important life domains that matter most for the individual person are inherently social in a cooperative or competitive sense.

Placed in this context, human health and well-being are closely related to successful self-regulation in a conducive social environment, and a stressful experience is likely to result from failed opportunities for successful agency, goal achievement, and reward experience in interpersonal exchange. The question then is what analytical concepts have been developed by the social and behavioral sciences to identify relevant socioenvironmental and personal triggers of recurrent stressful experience. The term psychosocial factor is used as a summary label to characterize the still-heterogeneous state of the art in this field. In other words, scientific progress has not yet resulted in a universally accepted taxonomy of stress-eliciting or stress-buffering social and personal (psychological) conditions.

This article presents a brief overview of some of the major concepts of identifying psychosocial influences

on stress and health. The two main procedures mediating this association are (1) enhanced neural/neuroendocrine/neuroimmune activation and (2) initiation of health-damaging behaviors.

There are multiple ways in which social and personal factors interact in influencing health and disease. It is useful to think of a stream of events where the most distal parts, the upstream factors, relate to the society at large or its main institutions (the macrosocial influences) and where the most proximal parts, the downstream factors, concern an individual's close or immediate social surroundings (the microsocial influences) and his or her personal ways of coping with the environment. In the following section, the discussion of psychosocial factors starts with the more distal parts of this stream and then proceeds to more proximal phenomena, including person characteristics. Finally, special attention is given to concepts that focus explicitly on the interaction between person and environment.

Overview of Psychosocial Factors Influencing Stress and Health

Macrosocial and Microsocial Factors

Every human society is characterized by a set of social values, norms, and institutions that are instrumental for the survival and growth of its members. If these values and norms lose their validity and meaning, or if society's patterns of social exchange become unpredictable and unstable, individuals tend to suffer from states of social anomie (lack of rules and orientations). A number of epidemiological investigations have explored the adverse effects on health produced by sociocultural instability, rapid social change, or a high level of social anomie. A majority of these studies found evidence of elevated risks of subsequent physical and mental illness.

One type of study was conducted in native societies that, after a long period of social stability, experienced rapid sociocultural transformation. As a consequence, less solidarity was witnessed among group members, and more deviant behavior, including violence, crime, and disruption of social ties, occurred. Equally distressing, the internalized cultural canon, which had been developed over many generations, broke down. Essential beliefs and ways of interpreting life were lost or fragmented. Under these conditions, cardiovascular risk factors, particularly hypertension, and coronary heart disease manifestation became more prevalent.

Similar observations were made by investigators who followed migrant populations from their original places to new sociocultural environments. Interestingly,

migrants who were able to maintain strong social ties with their traditional groups in the new environment were more likely to be protected against subsequent health risks compared to migrants who deprived themselves from these traditional bonds. This observation led to the conclusion that a stable social network and a particular quality of social exchange, termed social support, may act as a protective resource in coping with stressful circumstances. Social support is defined as the experience of, or access to, social relationships that offer mutual understanding and trust and that recurrently elicit positive emotions.

There is now convincing evidence that negative health effects result from social separation and social isolation, either due to loss of a loved one or due to poor opportunities for developing or maintaining relationships. Again, under these conditions, social support is less likely to be experienced and thus a strong psychosocial resource against stress is lacking.

While close social ties and social support denote downstream phenomena close to the intimate experiences made by individual persons, the more distal, macrostructural conditions of participating in the social fabric were shown to affect health as well. In particular, disinvestment in social capital was found to exert strong effects on morbidity and mortality at the level of whole populations. The term disinvestment in social capital describes a decline in reciprocal social exchange in neighborhood and community life, including a lack of solidarity and trust. For instance, when an area has a higher level of poverty, less investments are made into shared resources of community life, and hostile encounters or competitive struggles are more frequent.

Disinvestment in social capital is one of several health-adverse developments resulting from widening social inequalities. The demonstration of an inverse social gradient of morbidity and mortality within and between populations in a large number of advanced societies must be considered one of the most consistent and important findings of modern social epidemiology: the lower a person's socioeconomic status (in terms of educational attainment, income, and occupational standing), the higher his or her risk of poor health. These differentials are substantial. For instance, mean life expectancy in countries such as Finland or the United Kingdom is shortened by 5 to 6 years among members of the lowest as compared to the highest socioeconomic status group. It is important to note that these social differentials in health are spread across the whole of the society rather than being concentrated on a deprived group at the bottom of the society. So what are the causes of relative social deprivation in health?

Research repeatedly came to the conclusion that access to or quality of health care is not the main cause, as might be expected. Rather, unhealthy behaviors and exposure to stressful material and psychosocial environments, including lack of appropriate resources, must be considered the main determinants of social inequalities in health in advanced societies. These latter conditions include poor living and working conditions, threats to, or experience of, unemployment and income loss, and unstable social networks. Under these circumstances of relative social deprivation, feelings of anger, disapproval, and hopelessness are more frequent, intense, and long-lasting, thus aggravating the burden of stressful experience (see later).

Person Characteristics

Clearly, not every individual reacts to stressful environments in the same way. On the one hand, specific genetic or psychosocial factors may protect a person from adverse effects on health even under highly demanding circumstances. On the other hand, a person's threshold of susceptibility may be very low, thus predisposing him or her to illness onset under conditions of moderate stress. With the introduction of methods of molecular medicine into epidemiological studies, important advances in identifying people at elevated risk of disease were achieved. For instance, combining sociological information on stressful life events with genetic information on specific polymorphisms of the serotonin transporter receptor gene was shown to improve the prediction of early onset of depression in young adults.

One direction of research has focused on psychological traits that predispose an individual to spend high levels of energy. This pattern is functional if demands or threats are faced. However, in less demanding contexts, this may harm the organism by recurrent excessive physiological activation. Originally, researchers were interested in so-called type A behavior, a complex of behaviors and emotions defined by excessive striving, competitiveness, hostility, and impatience. Type A individuals were identified on the basis of specific psychomotor and speech characteristics, such as unrest, hectic, inability to relax, loud speech, and intrusive behaviors. As can be expected from a stress physiological perspective, excessive sympathoadrenergic arousal predisposes these individuals to cardiovascular dysfunction and disease.

Today, however, refined concepts following this direction of research are more successful in predicting future cardiovascular risk. One such concept concentrates on cognitive and affective components of hostility. The former include negative beliefs about

people and negative attitudes toward others, such as cynicism and mistrust, whereas the latter focuses on a frequent and intense experience of anger. A high level of hostility was found to promote health-adverse behaviors such as smoking and alcohol use in adolescence and young adulthood. Moreover, increased sympathetic function in combination with decreased parasympathetic function was observed. This observation could explain at least part of the direct statistical associations between hostility and coronary heart disease incidence that have been reported from several studies.

A similar approach emphasizes cognitive-motivational mechanisms of excessive energy spending. People characterized by overcommitment when facing demands tend to misjudge (e.g., underestimate) challenging stimuli and to expose themselves to multiple obligations. This may be due to their strong desire to control or dominate their environment, to exceed others, and to experience approval. For instance, workaholic behavior in occupational contexts can be interpreted in this context (see later). After a period of continued overcommitment, these individuals are susceptible to a state of vital exhaustion and psychophysiological breakdown, particularly when confronted with loss of control and failure. Overcommitment has been identified as a cardiovascular risk factor in epidemiological and experimental investigations.

A second line of research demonstrates adverse health effects of passive behaviors and associated low levels of energy spending. Importantly, inhibition or withdrawal of activity due to depressive mood and cognitions of helplessness and lack of self-esteem was found not only in reaction to but also preceding any experience of severe threat or loss. Some investigations conclude that individuals characterized by these psychological traits are at elevated risk of suffering from reduced immunocompetence and its pathophysiological consequences. Thus, over- and underactivation of a person's potential of vital energy in relation to self-regulating processes affect health at more fundamental, cellular and subcellular, levels, e.g., by increasing endogeneous oxidation and decreasing DNA repair capacity.

Although these behavioral patterns are influenced, to some extent, by genetic predisposition, evidence indicates that socioenvironmental factors have a strong impact on gene expression via methylation of DNA. Again, combining research on epigenetic processes with sociobehavioral research has promise for advancing the frontiers of knowledge.

In conclusion, distinct personal traits have been identified that must be considered psychological risk factors or protective factors. Protective factors

include a sense of mastery and self-efficacy (i.e., positive beliefs about one's agency) and favorable self-esteem, often paralleled by optimism and trust. Risk factors, as evidenced earlier, include overactive behaviors such as hostility, overcommitment, and excessive striving. These traits carry the risk of precipitating feelings of frustration and helplessness and triggering states of vital exhaustion. Moreover, risk factors include those cognitive, motivational, and affective traits that predispose individuals to withdraw from activity, to experience low levels of personal control and self-esteem, and to suffer from depressive mood and negative attributional style.

Person–Environment Interaction

Traditionally, the disciplines of medical sociology and social epidemiology have emphasized the role of socioenvironmental factors in health and disease, whereas medical psychology and psychosomatic medicine have stressed the importance of personality factors. Therefore, despite the obvious need for a more comprehensive analysis, few attempts were made to combine the two disciplinary approaches. Of these attempts, two developments deserve special attention.

First, in a period of declining impact of psychoanalytic thinking on etiological research, new interest emerged in understanding how socioenvironmental and personal factors interact in promoting health and triggering disease in a life course perspective. For instance, birth cohort studies demonstrate that adverse social circumstances of parents at the time of their children's birth increase the risk of premature mortality in children's later life. Explanations for this refer to elevated vulnerability during pregnancy and experience of cumulative cognitive, behavioral, and social disadvantage during childhood.

Among early psychological risk factors, a disturbed pattern of attachment between mother and child in infancy was shown to be of particular significance for later well-being. However, favorable social circumstances in childhood can compensate for these deficits to some extent by promoting children's resilience.

A second line of extensive research on how person and environment interact in producing stress-related disease has been concerned with the impact of working life on health. In contemporary societies, the work role still defines one of the crucial social roles in adulthood with powerful effects on successful or unsuccessful self-regulation. The adverse effects of job loss and related social isolation on health were mentioned earlier. Additional findings demonstrate that among low-status members of the workforce, stressful, health-damaging jobs in terms of a combination

of high demands and low control are more prevalent. In this context, the model of effort–reward imbalance at work is of interest, as it explicitly combines situational and person characteristics.

This model claims that lack of reciprocity between costs spent and gains obtained at work (high-cost/low-gain conditions) defines a state of emotional distress with special propensity to autonomic arousal and neuroendocrine stress response. Effort at work is spent as part of a socially organized exchange process to which society contributes in terms of rewards (money, esteem, and career opportunities). An imbalance between effort and reward is maintained if no alternative choice is available in the labor market. Moreover, people characterized by a high level of overcommitment and related cognitive distortion of demand appraisal (see earlier discussion) are equally prone to experience an effort–reward imbalance. Prospective epidemiological studies documented that stressful work in terms of high effort, low reward, and low control doubles the risk of incident fatal or nonfatal cardiovascular disease. In addition, onset of depression is more likely to occur.

Implications for Intervention

This article documents a solid body of research on the role of distinct psychosocial factors in triggering stress-related disease (risk factors) and in promoting health (protective factors). It highlights that both upstream (macrosocial) and downstream (microsocial and personal) factors are important in explaining elevated risk of morbidity and mortality. Finally, a combined approach focusing on person–environment interaction, including analyses of epigenetic processes, holds special promise for advancing scientific understanding and its consequences for prevention.

At all levels discussed so far, implications for intervention are obvious. At the macrostructural level, however, it is difficult to imagine how a reduction in the amount of relative social deprivation can be achieved. Policy measures such as limitations in income inequality, labor market regulations, and allocation of means to improve social capital can hardly be realized on the basis of anticipated health gain.

A more realistic approach toward intervention concerns the mesosocial level. For instance, several theory-based concepts of workplace health promotion have been implemented and evaluated. Reductions in blood pressure, heart rate variability, and levels of stress hormones and atherogenic lipids are examples of favorable health outcomes following task reorganization with enlarged decision latitude, improved social support, and improved leadership skills of superiors.

Similarly, more comprehensive intervention programs at the level of community, neighborhood, or school are being developed. Some of these programs pay special attention to sustained health gain in socially deprived groups or in high-risk groups. Examples are early-childhood family education programs, preschool programs, and adolescent health promotion activities. Improving successful parenting in socially deprived families was found to strengthen children's cognitive and emotional development.

Finally, an obvious level of intervention concerns the microsocial and personal level. Several behavioral intervention techniques have been developed and tested in both primary and secondary prevention. These include stress management, promotion of self-control and self-efficacy, personal empowerment, and an increase in social skills and coping effectiveness. These techniques proved to be particularly successful in reducing health-adverse behaviors such as unhealthy diet, smoking, alcohol, and drug consumption. In addition, the provision of social support and the formation of self-help groups are instrumental in reinforcing newly acquired attitudes, motivations, and behaviors. In summary, a rich potential of interpersonal and behavioral intervention approaches is now available that supplements traditional biomedical treatment techniques and that provides new opportunities for primary and secondary prevention. It is important to emphasize that this potential is based on scientific evidence obtained from pioneering research on psychosocial factors, stress, and health.

Glossary

Neurogenic essential hypertension
Major depressive disorder

Panic disorder

Elevated blood pressure initiated and sustained by a characteristic elevation in sympathetic nervous activity.

A common and severe mental illness characterized by feelings of hopelessness, helplessness, and worthlessness; often accompanied by suicidal thoughts.

A distressing and disabling condition with patients experiencing recurrent episodes of unexpected intense anxiety of sudden onset.

Mechanisms Underlying Coronary Heart Disease and Myocardial Infarction and Possible Relationship to Stress and Behavior

Sympathoadrenal Function in Panic Disorder

Sympathoadrenal Function in Major Depressive Disorder

I was walking along the road with two of my friends. Then the sun set. Then the sky became a bloody red and I felt a tinge of melancholy, a sucking pain beneath my heart. I stopped, leaned against the railing, dead tired. Over the blue-black fiord and city hung blood and tongues of fire. My friends walked on and I stood again trembling with fright. And I felt as if a loud unending scream were piercing nature. – Edvard Munch

Mechanisms Underlying Coronary Heart Disease and Myocardial Infarction and Possible Relationship to Stress and Behavior

Over recent years, substantial advances have been made in delineating the causes of coronary heart disease. At a community level, the importance of high blood pressure, tobacco smoking, and abnormal blood lipids as causal factors is well established. Recent epidemiological studies also point to an association between psychosocial stressors and increased risk of development of acute myocardial infarction. Mechanistically, the relevant issues linking psychosocial stress and acute cardiac events are whether stress, in one of its numerous forms, can (1) lead to the development of hypertension, (2) cause or aggravate atherosclerosis, and/or (3) trigger a cardiac event in the presence of existing atherosclerosis.

Relation of Stress to the Development of Hypertension

The importance of hypertension in the development of left ventricular hypertrophy, myocardial infarction, heart failure, and sudden death is well established. Indeed, over 90% of patients with heart failure in the Framingham study had a history of hypertension. The longitudinal studies of Timio and colleagues, examining hypertension development and cardiovascular morbidity and mortality in cloistered nuns, provide persuasive evidence linking the stress of daily life to the development of high blood pressure. Essential hypertension is commonly neurogenic, initiated and sustained by the sympathetic nervous system. While activation of the sympathetic nervous system outflows to the kidneys, heart, and skeletal muscle in hypertensive patients has been well documented, a second neural mechanism, reduced reuptake of the sympathetic neurotransmitter, norepinephrine, is also operative. Reuptake of norepinephrine into sympathetic nerves after its release terminates the neural signal. A fault in transmitter inactivation augments the effects of sympathetic nerve traffic. For the sympathetic nerves of the heart, approximately 95% of released norepinephrine is recaptured, so that the heart

is more sensitive than all other organs to impediments in transmitter reuptake. Other cardinal signs of stress common to patients with neurogenic essential hypertension include activation of brain noradrenergic pathways and epinephrine release from the heart.

Relation of Stress to the Development of Atherosclerosis

There exist numerous population studies indicating that psychological disturbances, particularly anxiety and chronic stress, can contribute to atherosclerosis development. In the workplace, insufficient self-regulation of workload, deadlines, and planning and direction of the work have been linked to risk of developing atherosclerosis. Low socioeconomic status or employment level is associated with increased plasma fibrinogen and von Willebrand factor concentrations. Endothelial function is considerably impaired following acute experimental stress.

Relation of Stress to the Triggering of a Cardiac Event

Cardiac sympathetic nerves are preferentially activated by mental stress It is important to realize that sympathetic nervous activity at rest and in response to stress is regionalized. For instance, with even relatively mild experimental mental stress, such as that induced in the laboratory by performing difficult mental arithmetic, the sympathetic nerves of the heart are markedly and preferentially activated, whereas activation of muscle vasoconstrictor sympathetic fibers predominates during the cold pressor test. Mental stress in patients with existing coronary artery disease has been demonstrated to cause anginal chest pain and inadequate blood supply to the heart. The effect of mental stress on cardiac sympathetic nervous activation is greater in the elderly. The importance of cardiac sympathetic activation in these contexts is highlighted by the demonstration, in experimental animals with narrowing of the coronary arteries, that direct electrical stimulation of the cardiac sympathetics is capable of causing electrical instability of the myocardium, triggering disturbances of heart rhythm and cardiac arrest.

General relation between activity of the sympathetic nerves of the heart and sudden death In a range of clinical contexts, stimulation of the cardiac sympathetic outflow has been demonstrated to contribute to myocardial infarction, ventricular arrhythmias, and sudden death. Activation of the sympathetic outflow to the heart is common in patients unexpectedly developing ventricular tachycardia and ventricular fibrillation. Furthermore, myocardial stunning due

to sudden emotional stress is associated with exaggerated sympathetic stimulation. Similarly, in patients with heart failure, there is a high level of stimulation of the cardiac sympathetic nerves, which is a proven determinant of sudden death. β -adrenergic blockers have been recently shown to increase survival in heart failure patients.

Direct relation between mental stress and sudden death in certain circumstances In a rare inherited heart condition, long QT interval syndrome, there is electrical instability of the heart muscle. Mental stress is one proven immediate cause of cardiac arrest in sufferers. Some research linking mental stress to sudden death is disputed because of disagreement over what constitutes a stress, and whether stress can be accurately measured. Recent research showing that rates of sudden, nontraumatic death in people with underlying coronary disease were markedly increased during catastrophic events is free of this criticism, as no finessing is needed in the psychological measurement of stress.

Sympathoadrenal Function in Panic Disorder

Debilitating episodes of recurring, often inexplicable anxiety afflict as many as 12% of the population. These attacks typically are unpleasant and may be accompanied by physical symptoms such as sweating, palpitations, tremor, and a sensation of suffocation. Given the prominent signs of sympathetic activation that occur during a panic attack, panic disorder patients find themselves at the nexus between cardiovascular and psychiatric medicine. It has until recently been felt that although panic disorder is distressing and disabling, it does not constitute a risk to life. Sufferers often fear that they have heart disease because of the nature of their symptoms, but have been reassured that this is not the case. Epidemiological studies, however, indicate that there is an increased risk of myocardial infarction and sudden death in patients with anxiety disorders. This increased risk extends even to premenopausal women, who in general have low coronary risk.

Somatic Sensitization as a Panicogenic Factor

Patients with panic disorder often exhibit hypervigilance to somatic sensations such as an irregular heart-beat or lightheadedness. Given the convergence of neural networks involved in processing viscerosensory and contextual information and their links with brain regions pivotal in the fear network, it is possible

that somatic sensation may be capable of triggering panic attacks. Such a concept is not without precedent. It has been known for some time that the presence of abnormalities of heart rhythm, supraventricular tachycardia in particular, can pre-date and in fact cause panic disorder. More recently, a very high rate of development of panic disorder was observed in patients with implanted cardiac defibrillators. Indeed, factors at play here seem to include the presence of cardiac symptoms and the enhanced vigilance that accompanies them.

Sympathetic and Adrenomedullary Function in Panic Disorder

Resting whole body, cardiac, and muscle vasoconstrictor sympathetic activity is normal in patients with panic disorder. While adrenal medullary secretion of epinephrine, measured by isotope dilution, is typically normal in these patients, there occurs a demonstrable release of epinephrine from the heart. It is probable that during the surges of epinephrine secretion that accompany panic attacks the cardiac sympathetic neuronal vesicles become loaded with epinephrine that is continuously co-released with norepinephrine in the interim periods between attacks. *In situ* synthesis of epinephrine, through activation within the heart of phenylethanolamine-n-methyltransferase (PNMT), perhaps induced by repeated cortisol responses during panic attacks, may also occur. In experimental models of stress, PNMT activation in the heart and other extra-adrenal organs has been demonstrated.

Norepinephrine Reuptake in Panic Disorder

As mentioned previously, reuptake of norepinephrine into sympathetic nerves after its release terminates the sympathetic neural signal. A phenotypic defect in norepinephrine transporter function has been described in patients with panic disorder. Such an abnormality in neuronal norepinephrine reuptake could sensitize the heart to sympathetic activation. The mechanism underpinning the defect in norepinephrine transporter function, and whether treatment modifies the activity of the norepinephrine transporter, remains unknown.

Sympathetic and Adrenomedullary Function during a Panic Attack

During panic attacks triggered cardiac arrhythmias, recurrent emergency room attendances with anginal chest pain and ECG changes of ischemia, coronary artery spasm in attacks occurring during coronary

angiography, and myocardial infarction associated with coronary spasm and thrombosis have been documented. The recurrent episodes of unexpected intense anxiety that characterize a panic attack are accompanied by a pronounced activation of the sympathetic nervous system and adrenomedullary secretion of epinephrine. A concomitant elevation in blood pressure and heart rate also occurs. The characteristic chest pain that occurs during an attack is additionally accompanied by the release of neuropeptide Y into the coronary sinus. Neuropeptide Y is a potent vasoconstrictor with the capacity to cause coronary artery spasm.

Sympathoadrenal Function in Major Depressive Disorder

Central Nervous System Neuronal Activity

The etiology of major depressive disorder (MDD) has been linked, variously, to brain monoaminergic neuronal dysfunction, alterations in monoamine receptor sensitivity, and stress-induced activation of the hypothalamic-pituitary-adrenal axis. The lack of demonstrated relationships between different clinical presentations and biochemical abnormalities has hampered the development of sensitive biochemical markers for MDD. A major difficulty in commonly used peripheral indices of a neurotransmitter (or neurotrophic factor) as an indicator of brain dysfunction is that these compounds are also produced outside the brain. For this reason, venous blood is directly sampled from the brain to study central nervous system (CNS) neurotransmitter turnover, using central venous catheters placed high in an internal jugular vein. Under these circumstances, arteriovenous differences in neurotransmitter concentrations can be extrapolated to estimates of brain production. The observation of global (i.e., noradrenergic, dopaminergic and serotonergic) reduction in both subcortical monoamine turnover and cerebral glucose utilization in patients with MDD is consistent with a reduction in CNS neurotrophic support in patients with MDD.

Depression as a Risk Factor for the Development of Cardiac Disease

There is strong evidence that patients with MDD are at increased risk of developing coronary heart disease. This elevated risk is independent of classical risk factors such as smoking, obesity, hypercholesterolemia, diabetes, and hypertension. The association is present in males and females, across different age groups and in subjects living in different countries. The risk of coronary heart disease is increased 1.5- to

2-fold in those with minor/subsyndromic depression and 3- to 4.5-fold in subjects with major depression. To put this into perspective, the strength of the association between coronary heart disease and MDD is similar to that with smoking and hypercholesterolemia. Also conclusively demonstrated is the adverse effect of depression in patients with heart failure and in patients following myocardial infarction, which materially increases mortality.

Sympathoadrenal Activity in MDD

While the mechanism of increased cardiac risk attributable to MDD is at present uncertain, activation of the sympathetic nervous system may be of prime importance. Chronic stress has been linked with MDD. Examination of indices of sympathetic nervous function in MDD has yielded conflicting results. Some studies indicate a tendency for both the urinary excretion and cerebrospinal fluid level of norepinephrine and its metabolites to be diminished, whereas other reports document elevated plasma levels of norepinephrine and increased rates of norepinephrine spillover to plasma in patients with MDD. It is likely that sympathoadrenal activation is present only in a subset of patients with MDD. Indeed, Gold and colleagues recently demonstrated elevated norepinephrine levels in both the CSF and plasma of patients with melancholic depression.

In addition to possible effects on blood pressure and myocardial stability, sympathetically mediated neural vasoconstriction may exert metabolic effects in skeletal muscle, impairing glucose delivery to muscle and causing insulin resistance and hyperinsulinemia, and in the liver, retarding postprandial clearing of lipids and contributing to hyperlipidemia. A trophic effect of sympathetic activation on cardiovascular growth, contributing to the development of left ventricular hypertrophy, may also occur. Left ventricular hypertrophy is an independent risk factor for cardiovascular morbidity and mortality.

Further knowledge of the mechanisms responsible for generating cardiac risk may pave the way for novel and perhaps relatively simple therapeutic strategies (e.g., low-dose aspirin, β -blockers) to be administered to those with MDD in order to modify cardiac risk. Indeed, defining therapeutic interventions that reduce cardiac risk will be an important step forward in alleviating the burden of depressive illness on the community.

Glossary

<i>Alexithymia</i>	Not reading emotions; an inability to identify and discriminate between specific emotions.
<i>Amygdala</i>	Paired almond-shaped nuclei that are part of the limbic system of the brain and are concerned with fear processing.
<i>Anabolism</i>	Rebuilding and repairing of tissues.
<i>Cushing's syndrome</i>	Hyperfunction of the adrenal cortex.
<i>Gastric mucosa</i>	The lining of the stomach wall.
<i>Hippocampus</i>	A paired seahorse-shaped structure that is part of the limbic system of the brain concerned with memory.
<i>Hypothalamic-pituitary-adrenocortical (HPA) system</i>	One of the two main stress response systems of the brain, which subserves the neural (neuroendocrine) control of glucocorticoid secretion by the adrenal glands. Among other actions, the glucocorticoids facilitate energy mobilization.

Definitions

When the concept of psychosomatic medicine was introduced in science it was founded in a medical discipline: psychiatry. Medical conditions (i.e., diagnoses) that were characterized by objective changes and that could be induced by psychological states were defined as psychosomatic. This early definition of psychosomatic included duodenal ulcer, ulcerative colitis, bronchial asthma, essential hypertension, rheumatoid arthritis, thyrotoxicosis, and neurodermatitis. Later definitions have been more focused on the individual's total state. According to such a definition, a psychosomatic condition is a state with somatic and psychological symptoms. The direction of causation is often difficult to establish. Thus, there may be psychological processes influencing somatic mechanisms as well as somatic phenomena that influence psychological states. The latter phenomenon has also been labeled somatopsychic.

Two early authors who were using the old way of defining psychosomatic were Franz Alexander (who was a psychoanalyst and a pupil of Sigmund Freud) and Flanders Dunbar. An important element in the efforts to diagnose conditions in the early days was the specificity concept. Specificity was used to label specific psychological processes that would be associated with specific psychosomatic diagnoses, e.g., a repressed cry in relation to an acute attack of bronchial asthma or an oral frustration during early childhood in relation to duodenal ulcer development in adult years.

A famous example of organic conditions that could be induced by psychological states was observed in the patient Tom, who had a gastric fistula. The fistula made the gastric mucosa available to the eyes of the researchers, which enabled the internists Harold Wolff and Stewart Wolf to conduct psychological experiments: they could study Tom's gastric mucosa while different states were induced in him. When long-lasting states of anger were induced, small ulcers arose, which were associated with elevated acid production, increased motility, and reddening of the mucosa. The opposite condition, a pale and passive mucosa with very little production of acid, was observed when Tom was in a state of long-lasting withdrawn and passive sadness.

Recently, discussion about peptic ulcer etiology has focused on *Helicobacter pylori*, a bacterium that is present in the gastric mucosa of most, but not all, patients with peptic ulceration. *Helicobacter pylori* seems to be necessary for the development of most peptic ulcers. Nevertheless, stress-induced variations in production of acid could increase the likelihood of ulcer development, especially in critical care

situations. That is, the effects of emotional or stress-induced changes in gastric acid production could interact with *Helicobacter pylori* to cause gastric ulceration in some individuals. Robin Warren and Barry Marshall were awarded the 2005 Nobel Prize for the discovery of *Helicobacter pylori*.

In the more modern and wider definition of psychosomatic, the attitude toward the patient's illness is central. If any condition could be more or less psychosomatic, all caregivers should ask themselves whether there are aspects of their patient's condition that could be psychosomatic.

Link with Stress Physiology and Epidemiology

The influence of stress physiology on theoretical modeling in psychosomatic medicine became evident when internists became interested in the field. When psychiatrists collaborated with physiologists and internists, some of the basic mechanisms were revealed, explaining why allergic reactions, wide swings in diabetes mellitus, worsening of hypertension, and many other conditions could be partly psychosomatic.

The next step in the scientific development of the field was taken by epidemiologists, who made it possible to describe psychosomatic conditions in persons outside the doctor's office: the total illness panorama. In this way it became possible to identify those who suffer from psychosomatic conditions but do not consult a caregiver.

Studies of extreme stress were initially an important part of the psychosomatic field, and this is also where the link between stress and psychosomatic medicine was established. In Style's general adaptation syndrome (GAS), stress was seen as the general reaction to a nonspecific challenge or adverse condition that was labeled a stressor (a factor that induces stress). According to this definition, stress is a reaction, and it is a general one. It is evident that this reaction induces arousal, which means that energy is mobilized. There are several parallel phenomena, all of which aid the body in the physical fight-or-flight response. Examples include lowered excretion of water and salt, decreased sensitivity to pain, and decreased inflammatory response in infections. Because energy mobilization (resulting in an elevated blood concentration of glucose and free fatty acid) has the highest priority, anabolism is downregulated. Anabolism is central to the body's central defense of all the organ systems that need constant rebuilding and restoration. If this goes on for a long time (e.g., several months), increased sensitivity to physical and psychological stress in bodily organs is the ultimate result.

This represents a more general theory in contrast to the specificity theory mentioned earlier. Another consequence of long-lasting demands for energy mobilization is that endocrine systems may change their regulatory patterns. One consequence could be that the production of thyroid hormones is stimulated. Thyroid hormones stimulate a long-lasting upregulation of the metabolic rate.

Disturbed regulation of the hypothalamic-pituitary-adrenocortical system (the HPA axis) has also been described in relation to long-lasting arousal. There seem to be at least three kinds of regulatory disturbances in the HPA axis:

1. Lack of inhibition of stimulation. Normally, cortisol inhibits higher centers in the HPA axis when it has been elevated for a long time. When this inhibition does not take place in the normal way, the levels tend to be elevated constantly.

2. Lack of response to stimulation of the HPA axis. This means that plasma cortisol levels are low and that the normal activation does not take place when the HPA axis is stimulated artificially.

3. Unstable levels. In this kind of disturbance, the plasma cortisol levels may be low at rest, but certain situations (that are specific to the individual) trigger a strong HPA axis reaction that may seem to be out of proportion to the importance of the trigger.

The first kind of regulatory disorder is typical of Cushing's syndrome and could be one alternative regulatory disturbance in psychiatric depression. Severe long-lasting psychiatric depression may be associated with constantly high cortisol levels; in most cases, however, the circadian rhythm is preserved.

The second kind of disorder has been shown to exist in a subgroup of patients diagnosed with chronic fatigue syndrome (CFS). Because at least one other group of patients, those with fibromyalgia, share some symptoms that are typical of this regulatory disorder with CFS patients, it is possible that part of the myalgia problem is that they also suffer from this disturbance. It should be pointed out, however, that CFS and fibromyalgia also have differences in symptomatology and that it is not known to what extent psychosomatic processes contribute to them.

The third kind of regulatory disorder is found in posttraumatic stress disorder (PTSD). The key element in the etiology of PTSD seems to be that the long-lasting extreme arousal level increases the number of cortisol receptors of the cell surfaces and also increases their sensitivity. Because the sensitivity is so high, only low concentrations of cortisol are needed to keep the system working at rest. This may be the reason why low serum cortisol levels are found at rest in patients with PTSD.

Disturbances in endocrine functions represent a more general theory that has been of central importance to psychosomatic medicine. Physiology has also contributed to the specificity theory, however. A recent contribution to cardiovascular psychosomatic medicine has been the hostility hypothesis, which states that subjects with a high degree of hostility and cynicism are more likely to develop a myocardial infarction at a relatively young age compared to other subjects. Hostility has been linked to disturbances in the production and blood concentration of serotonin.

Psychosocial processes are mostly not capable of inducing organic illnesses by themselves. There are other pathogenic processes involved that may have a genetic origin. One example that has been discussed recently is the role of the immune system in the etiology of thyrotoxicosis. Excessive production of some of the immune system's interleukines causes abnormal regulation of function of the thyroid gland, resulting in either thyrotoxicosis or hypothyroidism. Still, long-lasting life changes do have a role in facilitating the onset of thyrotoxicosis.

Social Environment

James P. Henry was one of the most active physiologists taking the position that the social environment has to be taken into account in the study of psychosomatic medicine. He represented a group of researchers who increased the understanding of psychosomatic medicine by taking into account both studies of colonies of animals whose social environments were manipulated and natural international variations across the human culture. One important finding was that blood pressure does not rise with increasing age in all cultures.

Gene Activation

Modern psychosomatic research has been influenced by the rapidly growing amount of knowledge about genes and gene activation. Genes that are of particular relevance to psychosomatic medicine are those that regulate monoamines such as thyroxine, noradrenalin, serotonin, and dopamine. This research explores mechanisms and importance of interactions between the environment and genes in the psychogenesis, for instance, of depression. An important landmark in these studies has been the prospective birth cohort study in New Zealand published by Caspi et al. A total of 1037 children were assessed every second year from age 3 up to age 15, every third year to age 21, and finally at the age of 26. Stressful life events occurring after the 21st and before the

26th birthday were assessed by means of a life history calendar. The risk of onset of depression after critical life events was shown to be related to a variant ("polymorphism") in the promoter (control) region of the serotonin transporter gene. One type of allele combination in this region is protective while another increases risk. These studies point at new directions in psychosomatic research.

Psychosomatic Attitude

The modern definition of psychosomatic is related to a treatment attitude toward the patients. The psychosomatic therapist is expected to consider social and psychological factors that may be of importance to the course of the patient's illness and to do this in all cases encountered. This of course means that any condition could be partly or totally psychosomatic. Such awareness should affect all medical treatment.

Difference between Behavioral Medicine and Psychosomatic Medicine

Behavioral medicine and psychosomatic medicine are similar to one another but are not identical. Behavioral medicine deals primarily with phenomena that are possible to record objectively, whereas psychosomatic medicine deals with intrapsychic phenomena as well. Psychosomatic medicine has been introduced mainly by psychiatrists and physiologists (biologists and medical doctors), whereas behavioral medicine has been introduced mainly by behavioral psychologists.

The therapeutic orientation has also been different in the two disciplines: whereas psychodynamically oriented treatments have dominated psychosomatic medicine, behavioral and cognitive psychotherapy has dominated behavioral medicine.

Brain Anatomy and Physiology

A major discovery in brain neurophysiology has changed the basic background of medicine. This is the fact that structural changes in the nerve cells of the hippocampus of the brain may occur as a consequence of traumatic experiences. Such discoveries have been made possible by new techniques for imaging the brain, building on principles such as magnetic resonance and positron emission. According to several studies, the volume of the hippocampus, a structure that is of great importance for the storage of basic memories, may diminish as a consequence of severe traumatic events that cause long-lasting changes in the concentration of several substances in the brain, with resulting PTSD.

Other neuroanatomical studies have shown that the interaction between emotions and cognition

could be localized as traffic between specific structures such as the amygdala (representing nonspecific arousal and anxiety) and hippocampus (memory). Studies have shown that subliminal visual stimulation (pictures presented so rapidly that the person does not become aware of what they represent) may induce activity in the limbic system, e.g., the amygdala. It is known that there are direct connections between the visual cortex and the limbic system, and the cortex may therefore be activated at a later stage than the limbic emotional system. Similar connections exist for auditory stimuli. Such knowledge is of great importance in explaining the fact that sub-conscious processes may induce strong psychosomatic reactions.

Studies of Life Changes

The basic theory behind studies of life changes in psychosomatic research was Selye's nonspecific stress theory. It was later formulated by Holmes and Rahe as a theory of demands for adaptation to any change. A system of life change units was constructed on the basis of average scores from individuals in the normal population on demands for adaptation to specific life changes such as death of spouse, loss of job, and residential move. This line of research has shown that a group of subjects with an accumulation of important life changes during a short period of time will have an increased number of illness episodes during the subsequent period. This association holds on a group level but it is quantitatively relatively weak. It is when coping patterns, and also the perception of the life change by the subjects themselves, are taken into account that predictions get stronger. During later years, studies have shown that for certain types of illnesses and physiological reactions, a distinction could be made between positive and negative life changes – with positive changes in some cases inducing improvement and negative changes inducing deterioration in health. Studies of life changes have been important to the practice of psychosomatic medicine. Particularly in chronic illness rehabilitation, it is very useful to make systemic explorations of ongoing life changes. The patients immediately understand the value of this method, and the exploration may lead to increased insight, which could be very useful. Discussions regarding life changes that the patient has experienced with a concomitant recording of physiological functions may strengthen the insight further.

A sociological school of life change research, represented by Brown and others, has concentrated on the objective aspect of life changes. Special schemes for recording objective aspects of life changes are being

used. By analyzing the structural meaning (not the perception) of a life change, these authors have shown that there is an independent contribution of the change itself to the risk of illness.

Coping and Behavior Patterns

The way in which the individual perceives his or her life situation is of profound importance to his or her health. A basic concept in psychosomatic medicine is alexithymia, an inability to identify and discriminate between specific emotions. According to the theory introduced by Sifneos, primary alexithymia arises when emotions have not had the possibility to develop in the normal way during childhood, with resulting partial or total inability to differentiate specific feelings such as joy, anxiety, sadness, and rage. Secondary alexithymia, however, may arise during major life crises such as traumatic experiences or severe illness episodes. Patients with pronounced alexithymia may be very difficult to treat with verbal psychotherapy, because they do not have access to effective interpretations of what happens in their bodies in relation to emotionally arousing situations. Educational programs are presently being tested. A related concept is *pensée opératoire*, operative thinking, and a propensity to describe practical acts rather than emotions, e.g., in crisis situations.

Another aspect of coping that has been of particular importance to psychosomatic medicine is type A behavior. It was originally described as a behavior pattern that was elicited in certain situations. The cardiologists Friedman and Rosenman had seen it in younger male patients with coronary heart disease. In early stages of the scientific development it was discovered that there were several distinct components in this behavior, such as excessive drive and ambition (to manage difficulties better than others against the worst possible obstacles), hostility/feeling of rush, and excessive work orientation. Later researchers have criticized the definition of general type A behavior and stated that cynical hostility may be the key component. Evaluations of type A behavior intervention programs in secondary coronary prevention have shown that successful long-term programs (mostly lasting for at least a year) for reducing type A behavior may reduce the risk of developing new episodes of coronary heart disease.

Psychosomatic Treatment

Psychosomatic treatment follows different traditions in different countries. In several countries, e.g., Germany, there are several academically based clinics

for psychosomatic treatment, mostly founded in psychoanalytical theory. In other countries, e.g., Sweden, it is believed that psychosomatic treatment should be part of good patient treatment on the whole, and therefore very few psychosomatic departments have been founded.

One of the key elements in psychosomatic medicine, from the time of Freud and his followers to today, has been alexithymia (see earlier discussion). Patients with long-lasting severe psychosomatic disturbances frequently suffer from early (childhood) disturbance of the emotional development. Chronic pain and chronic gastrointestinal functional disorders are examples of conditions that have been shown to be associated with traumatic childhood circumstances. It has been found that traditional verbal psychotherapy may be very difficult in such cases. Alternatives have been tried that could surpass verbal barriers. Such therapies could build either on direct bodily sensations or on indirect ways of helping the patients gain useful insight into emotion-body relationships. One such alternative is the use of arts that could be used either impressively or expressively. An example of the impressive use of music is guided imagery and music (GIM). GIM has been shown to have not only temporary but also long-term effects on endocrine systems. In an uncontrolled study of the use of dance, music, painting, or drama of patients with long-lasting (2 years in most cases) psychosomatic disorders, it was shown that the use of expressive arts can be helpful in gaining useful insight into the interplay between emotions and bodily symptoms. Experiences of art are often less guarded than verbal communications. In this study, the patients went through a catharsis phase of the treatment, mostly during the period 6 to 12 months after the start, in which strong emotions had been evoked and there was evidence of general physiological arousal. The art experiences were often helpful in creating turning points in the therapy.

Liaison Psychiatry

For a long time there has been a strong link between psychosomatic medicine and liaison psychiatry. In liaison psychiatry, specially trained psychiatrists work continuously in somatic medicine and have a special responsibility for patients with psychosomatic conditions. Liaison psychiatry includes areas in which psychological processes are of particular importance to healing of wounds and acceptance of transplants. The latter two areas are of particular importance to surgical wards. Studies during later years have shown that excessive long-lasting mobilization of energy prolongs the healing of wounds.

Final Comments

Psychosomatic medicine has developed rapidly since the introduction of the discipline. Specific theories along with general theories have been tested. In modern psychosomatic medicine there is growing awareness that the social environment is of great importance and also that the etiological processes are very complex. Interactions between physical, chemical, and biological agents (e.g., infections, such as *Helicobacter pylori*) and psychosocial processes cause long-lasting psychosomatic conditions.

Glossary

<i>Counseling</i>	A professional interpersonal process that overlaps with psychotherapy but that has as its focus specific problems or adjustments.
<i>Psychoanalysis</i>	A theory of mental development embracing the concepts of the unconscious as a determinant of behavior, the use of defenses against the emergence of unconscious tendencies, and the phenomenon of unconscious transference of relationships with past objects to present relationships.
<i>Psychoanalytic practice</i>	The application of a psychotherapeutic method characterized by emphasis on free association, transference, and interpretation, aimed primarily at producing greater self-awareness.
<i>Psychotherapy</i>	An interpersonal process designed to bring about modifications of feelings, cognitions, attitudes, and behavior that have proven to be troublesome to the person seeking help from a trained professional.
<i>Stress disorder</i>	A mental disorder as defined by the International Classification of Diseases and the Diagnostic and Statistical Manual of the American Psychiatric Association.

Introduction

Psychotherapy is an interpersonal process designed to bring about modifications of feelings, cognitions, attitudes, and behavior that have proven to be troublesome to the person seeking help from a trained professional. This time-honored definition, attributed to Strupp, is a condensation of the key issues of psychotherapy. A wider view of psychotherapy includes the concept of helping a person to become his or her best possible self. Psychotherapy is a major component of most stress management programs and treatments for stress-related disorders.

Psychotherapy as an Interpersonal Process

That one person can influence the way another feels, thinks, and behaves is a fundamental assumption in most cultures. Such influence can be either good or bad. The notion that language is involved is implicit. Psychotherapy is a professional refinement of this language-based interpersonal process. It usually consists of a verbal exchange, but may involve writing or dramatic performance as well.

Modification of Feelings, Cognitions, Attitudes, and Behavior

Psychotherapy aims at the modification of existing feelings, cognitions (thoughts), attitudes, and behavior. Psychotherapy avoids the issue of whether these phenomena are inherited or acquired, and it takes as given that they exist and are potentially modifiable. Nevertheless, there is an implied recognition that there has already been a process at work creating these phenomena, with or without the conscious awareness of the individual. Psychoanalysis and its derivative psychotherapies take account of the origin of these phenomena, but focus on their current manifestation in the transference, that is, on what occurs between the patient and therapist.

Troublesomeness of Phenomena

Disturbances of feelings, thoughts, and behavior are universal experiences. Psychotherapy deals with people who feel troubled by their experience of these phenomena, that is, people who are stressed and distressed. They may feel it directly, for example, in the case of depressed mood, or indirectly, for example,

when an upsurge of aggression leads to relationship problems or trouble with authorities. Stressed people are usually troubled by disturbance of their daily function. For the physically ill, stress may be troublesome because of its impact on their illness. The relationship between mental and physical states is clearest in the case of clinical depression. Having an episode of clinical depression at some stage in life at least doubles the risk of developing a major medical disorder such as coronary heart disease, stroke, or diabetes. Once these disorders develop, the presence of depression doubles the mortality rate and greatly increases morbidity and health-care costs, as do poor social support and poor social integration.

The Person Seeks Help

Psychotherapy as a form of interpersonal influence depends on and makes use of the fact that the troubled person seeks out help. In psychotherapies based on psychoanalytic theory, this action is central to the concept of transference. The person seeking help has expectations of the therapist, based on both the realistic knowledge of what the therapist has to offer and on unrealistic expectations transferred to the person of the therapist on the basis of relationship with other key figures in the person's life. This illustrates the fact that there is much going on in a psychotherapeutic relationship that is unsaid yet represented in language at some level and experienced as feelings and attitudes.

Help Is Sought from a Trained Professional

What differentiates psychotherapy from other forms of positive interpersonal influence is that it is offered within a formal set of parameters with an explicit basis for its conduct. That does not necessarily mean that it is valid, but it does mean that it is open to scrutiny. The trained professionals come from a variety of backgrounds, including medicine (particularly psychiatry), psychology, social work, nursing, and education. Specific training in psychotherapy is usually taken as a postgraduate course. There are institutes within the field that are devoted to training in and the development of psychotherapy. It is this postgraduate training that produces the skills and attitudes that differentiates professional psychotherapy and professional counseling from the informal counseling that many professionals provide in their everyday work.

Another implication of the involvement of a trained professional is that a code of ethics applies. Such codes are likely to include statements about respect

for patients or clients, their values, their beliefs, their uniqueness, and their right to self-determination. In particular, psychotherapists are obliged to respect and take account of cultural factors and to avoid discrimination on the basis of such factors and beliefs. There is a consensus that the practice of professional psychotherapy requires ongoing supervision of some sort, in which there can be scrutiny of the application of these ethical principles. Supervision also addresses adherence to protocols. A special feature of supervision of psychoanalytic psychotherapy is that there is also scrutiny of the therapist's reaction to the patient – called countertransference.

What Is the Difference between Psychotherapy and Education?

All forms of professional psychotherapy contain an educational component, as does counseling, even though education is not their aim. Even psychoanalytic psychotherapy, which deemphasizes the didactic component, provides a model of thinking that the patient or client may find that they have adopted. In the sense that psychotherapy is explanatory, it is educational. The difference between psychotherapy and education lies in the fact that psychotherapy deals specifically with those matters that trouble the person requesting it and uses techniques specific to that issue. However, it must be acknowledged that much of modern teaching, with its individualized programs and greater sense of responsibility for the wider concerns of the student, is psychotherapeutic in nature. Many educational institutions are recognizing this by introducing mental health studies into their training. This does not mean that educators will become professional psychotherapists; that would require postgraduate training.

Stress Management

Stress management is the name given to an intervention offered increasingly and to a wide variety of target populations, including those at risk of stress and those who have experienced it. Often given in a group setting, it most frequently includes specific psychotherapy techniques but also imagery and relaxation techniques and an educational component.

The Schools of Psychotherapy

Psychoanalytic Psychotherapy

Professional psychotherapy has its historical roots in the development of psychoanalysis at the end of the nineteenth century. Psychoanalysis as a practice is a form of psychotherapy. Psychoanalytic

psychotherapy is a term used to describe all forms of psychotherapy that are based on the principles of psychoanalysis. The expressions dynamic and psychodynamic can be taken as a synonym for psychoanalytic. The distinction between psychoanalysis and psychoanalytic psychotherapy is indistinct, but it centers on issues of frequency, technique, and goal. Psychoanalysis is usually more intense in frequency and length. Psychoanalytic psychotherapy uses modified analytic techniques and may mix them with nonanalytic techniques. Psychoanalytic psychotherapy is often more problem-focused and may be explicitly supportive.

The issue of whether a form of psychotherapy is described as supportive is a complex one. All psychotherapies are supportive in the sense that they offer a containing framework in which a patient or client can deal with his or her stresses and lessen his or her distress. The concept of nondirectiveness is more pertinent. In psychoanalytic psychotherapy, interventions that contain suggestions or directions are usually avoided because they may interfere with the achievement of greater self-awareness, a major goal of psychoanalytic practice.

As the field of psychoanalysis developed various theoretical streams, so there developed different schools of practice of psychoanalysis and its derivative psychotherapies. Brief dynamic psychotherapy is associated with the names Malan, Sifneos, Strupp, Davanloo, Mann, and Horowitz. Klein, Winnicott, Balint, and Guntrip pioneered object relationships theory and practice. Kohut developed self-theory. Lacan emphasized the linguistic basis of the structure of the unconscious; schools of psychoanalysis based on his teaching have wide support in Europe and South America. Jung, with his emphasis on universal symbols, spawned persisting schools of psychoanalysis.

Psychotherapies Related to Psychoanalysis

Other theorists such as Carl Rogers, Aaron Beck, and Harry Stack Sullivan focused on aspects of the subjective and cognitive experiences with which psychoanalysis dealt. They and others developed forms of psychotherapy based on their theories.

Experiential therapy Client- or person-centered therapy, existential therapy, Gestalt therapy, and emotional-expressive therapies are the most well-known examples of experiential therapy. They have in common the assumption that human nature is growth-oriented, and they focus on subjective experience. For instance, client-centered therapy is described by Rogers as having parallels in existentialism. It

emphasizes the autonomy of clients (and thus avoids use of the term patient). It also emphasizes the attitudinal qualities of the therapist; warmth, empathy, and genuineness.

Cognitive therapy Cognitive therapy assumes that people can develop automatic erroneous thought patterns and beliefs of which they are unaware and that they consequently think and behave in ways that are irrational. Albert Ellis developed the concept of cognitive restructuring in his rational emotive therapy. Beck developed a similar technique, which is the basis for that used by therapists today, in which the patient or client is helped to identify these automatic thoughts and to challenge them, using what has been described as a Socratic dialog. There are both psychoanalytic and phenomenological underpinnings to the therapy. Ryle has developed cognitive analytic therapy, which emphasizes the psychoanalytic component. Analyses of transcripts of therapists using cognitive therapies show that they incorporate elements of other therapies as well. The constructs of behavioral therapy are often so interwoven with those of cognitive therapy that the term cognitive-behavioral therapy has come to be used. Cognitive-behavioral therapy is a major component of stress management programs and of interventions for acute and chronic traumatic stress disorder. It is widely used in the treatment of psychiatric disorders in general.

Interpersonal psychotherapy Interpersonal psychotherapy is an eclectic blend of traditional clinical approaches that has its roots in the work of Sullivan and was operationalized by Gerald Klerman and colleagues. It focuses on current interpersonal issues, particularly those related to grief, interpersonal role disputes, role transitions, and interpersonal deficits. It is, thus, particularly suited to those experiencing stress. It is a brief form of therapy, originally used for the treatment of depression but now applied to many other forms of distress. It, together with cognitive-behavioral therapy, was found to be as effective as antidepressant medication for the treatment of moderate depression in a large study conducted by the National Institute of Mental Health in the United States. Psychodynamic interpersonal therapy emphasizes the use of psychodynamic techniques. It has been shown to be both efficacious and effective in the physically ill; that is, it works in practice as well as in experiments.

Behavioral Therapy

Behavioral therapy has its roots in classical learning theory, with which the names of Pavlov and Skinner are associated. It is also influenced by Bandura's theory of socially determined learning or modeling.

Watson and Wolpe's early clinical work has now been refined and operationalized into a therapy that focuses on current determinants of behavior and draws on the principles of learning to develop individual treatment strategies. Behavioral therapists are aware of the fact that they cannot avoid completely the issue of the meaning of the behavior targeted or the meaning of the relationship between the therapist and the patient.

Methods of Delivery of Psychotherapy

Psychotherapy can be delivered at all ages, and most types of psychotherapy are applicable to all age groups. Melanie Klein and Anna Freud were pioneers of child psychotherapy. There is an emerging discipline of old age psychotherapy.

Individual Therapy

Individual or one-to-one psychotherapy is the commonest application of psychotherapy, but psychotherapy in small groups is an important form.

Couples Psychotherapy

Couples psychotherapy, for those in a relationship, is used by therapists of most schools of psychotherapy. Many therapists use an eclectic approach, combining elements of various techniques. Sexual issues are often an important focus.

Family Psychotherapy

Family psychotherapy, or family therapy as it is now known, has its roots in psychoanalytic theory. It began with the work of Bateson and colleagues in the 1950s on the role of the family in cases of schizophrenia. Salvador Minuchin and colleagues developed techniques based on a psychoanalytic construct of the family, which focused on ways in which one member could be carrying the anxiety for the whole family. More recently, family therapy has been strongly influenced by systems theory. The construct of family is changing rapidly, and given that each member of a family may come with different needs, family therapists have to adapt their technique to the situation.

Group Psychotherapy

Group psychotherapy can be said to have originated during World War II. Psychoanalytically orientated psychiatrists such as Foulkes and Bion used it in England to manage stress-related cases of neurosis more efficiently. The concepts and techniques that they developed are influential today. The Tavistock Institute in the United Kingdom has pioneered models

of applied psychoanalysis for work groups trying to understand their social task. Such work forms part of stress management programs. Other schools of psychotherapy have developed group techniques. In the United States, Rogers extended his client-centered therapy to its application in encounter groups. Lewin developed methods for use in nonclinical situations. Behavioral therapy (e.g., for phobias) can be delivered in groups.

The Efficacy of Psychotherapy

Studies on the efficacy of psychotherapy for stress disorders as defined by international classifications are limited in number. However, the vast literature on the efficacy of psychotherapy in general is highly pertinent because it addresses the issue of stress by implication. Those diagnosed as having depression or anxiety, the most frequently addressed disorders in the research literature, are likely to have declared stress to be their major symptom, and this will have been acknowledged by their clinician when translating symptoms into a named problem or disorder. Furthermore, even when a primary diagnosis of a stress disorder is made, it is highly likely that a simultaneous diagnosis of depression, anxiety, or substance abuse will also be made. Personality disorder is another common comorbidity. The diagnoses of depression and anxiety imply distress, and the seeking of therapy certainly does so. These conditions, rather than the stress, may be the targets of psychotherapy. However, the exploration of perceived stressors and their effects forms an important part of all psychotherapies.

Overview

Health-care providers and consumers in general seek evidence of the efficacy of psychotherapy and justification of its cost. The empirical study of a therapy as complex as psychotherapy, applied as it is to such a wide range of problems and people, is fraught with methodological difficulties. Nevertheless, these difficulties have been addressed sufficiently well for Lambert and Ogles, in their review of efficacy and effectiveness studies, to conclude that many psychotherapies have been shown to have demonstrable effects on clients in clinical trials that are statistically significant and clinically meaningful and that speed up the natural healing process as well as providing coping strategies for future use. Although some clients may achieve meaningful results after brief psychotherapy (21 sessions), many need at least 50 sessions. Other conclusions were that the effects of therapy tend to be lasting, that psychotherapy patients show gains that surpass those resulting from placebo

controls or no treatment, that psychotherapy can be cheaper than medication, and that clients treated with psychotherapy show 25% less medical service utilization. However, they also conclude that average positive effects mask considerable variability in outcomes, that not all are helped, and that some are harmed by inept or inappropriate application.

Systematic and Meta-Analytic Studies

These conclusions were based on studies conducted over the past 80 years. Many of the earlier ones were naturalistic studies of therapy and follow-up. Some used qualitative research of individual cases, a technique now much refined and becoming increasingly important in the study of human behavior and experience in general. These techniques are particularly useful for examining the process of psychotherapy and the experience of patients or clients. Many of the recent studies are experimental; that is, a research plan is developed and clients are recruited for participation and follow-up, with monitoring of therapists as well. Systematic overviews of experimental studies group those that meet strict criteria for inclusion, such as the requirement of random allocation of clients to a treatment or control arm (randomized controlled studies, RCTs). Both qualitative and quantitative reanalyses may be applied. The statistical technique of meta-analysis is often used. It has methodological problems, but it is generally accepted that it provides a useful way of summarizing studies, albeit one that must be supplemented by more qualitative analyses. Early meta-analytical studies found that the average treated person is better off than 80% of the untreated sample (effect size of 0.85 standard deviation units). Lambert and Ogles conclude that studies since then, which include those on other large samples and a reworking of the original study and use of more sophisticated statistical techniques, have supported that finding in general but find lower but still clinically significant effect sizes (0.4–0.6) for both specific and general measures of outcome. The analyses on which these conclusions are based include studies on a wide range of therapies, including all of the mainstream ones, for specific disorders such as anxiety and depression and for general problems such as those of stress and personality. A wide range of severity of psychopathology is included. By way of perspective, effect sizes are similar to those found for the use of antidepressants in depression and pharmacological treatment of anxiety.

With respect to stress and its disorders, Ehlers and Clark conclude that systematic reviews and meta-analyses show that, contrary to the commonly held view, single-session individual debriefing does not

reduce distress and is not effective in preventing posttrauma symptoms. However, a course of up to 16 psychotherapy sessions may be more effective than supportive counseling in ameliorating the severity of acute symptoms and reducing subsequent posttraumatic stress disorder (PTSD), a chronic condition. Bradley et al., in their systematic review of psychotherapy for PTSD, conclude that substantial effects are found for psychotherapeutic intervention, with the majority of individuals showing improvement that was clinically meaningful; this was sustained for at least 6 months.

Which Therapy for Which Patient?

The question of which therapy is best for which client is only slowly being resolved. Relationship factors (trust, warmth, acceptance, and human wisdom) are probably crucial, even in the more technical therapies that generally ignore them. In fact, it is becoming clear that therapists in clinical trials as well as in practice are eclectic in their adaptation of therapy to suit client profiles. Lambert and Ogles conclude that differences in outcome between various forms of therapy are not as pronounced as might have been expected and that it is premature to favor the so-called empirically supported therapies over others. (This term refers to a movement that advocates that only those therapies with proven experimental support should be taught and funded.) Courses of psychotherapy may be shown to be effective in clinical trials, but they are not as efficient in clinical practice, partly because they are too short. Emerging naturalistic studies show a dose–response relationship such that long-term therapy is required, at least to the point of complete resolution of symptoms.

As previously discussed, stress and related disorders constitute risk factors for the development of physical illness and its outcome. Some work has been done on specific psychotherapy techniques for patients with physical and psychological comorbidity. Studies mainly focus on psychoeducational interventions. Health education and stress management programs produce significant positive effects on blood pressure, cholesterol, body weight, smoking behavior, physical exercise, and eating habits. Psychotherapy for depression in diabetes is effective in relieving symptoms and improving control. Early trials of psychotherapy in patients with cancer showed an increase in both well-being and survival time. Improved physical treatments for cancer and the greater availability of psychosocial treatments may explain why later studies are finding no differences in survival time, despite improvement in well-being and quality of life.

What Are the Active Ingredients of Psychotherapy?

The work of Pennebaker and his colleagues has shown that the writing down of accounts of stressful experiences is accompanied by better outcome than is achieved by writing about nonemotional matters. This supports other evidence that suggests that affective experiencing – catharsis – may to be an important ingredient of psychotherapy. Cognitive mastery, making sense of what is happening, also seems to be important. A focus on strategies for behavioral control is the third major factor identified so far. But there is an enormous amount of research that needs to be done if the active ingredients of psychotherapy are to be dissected out and the question “Which therapy for which client by which therapist and how much of it?” is to be answered. Consistent with this realization, researchers are returning to a focus on the ingredients of psychotherapy: what the therapist and patient actually do, and what goes on between them. Systematic reviews and meta-analyses will help answer the questions, but the medical model on which they are based is insufficient to address this most human of experiences, that of someone’s seeking help from a trained professional and entering an interpersonal process designed to bring about the modifications of feelings, cognitions, attitudes, and behavior that have proved troublesome to the person or, indeed, an individual’s seeking greater self-awareness as a way of fulfilling him- or herself better in his or her personal and social commitments.

Treatment as Protection against Stress and Psychosis

Glossary

<i>Brief psychiatric rating scale (BPRS)</i>	One of the most widely used rating scales, nationally and internationally, for measuring psychiatric symptoms at baseline and for assessment of change over time. The BPRS allows for the rapid assessment of symptoms such as depression, anxiety, delusions, and hallucinations.
<i>Cognitive appraisal</i>	An individual's evaluative thought process that instills a life event or situation with a particular meaning.
<i>Coping response</i>	Cognitive and behavioral efforts used to master, tolerate, and reduce the demands of stressful events that tax or exceed an individual's resources.
<i>Expressed emotion (EE)</i>	Attitudes and feelings expressed by a relative during family interactions; an individual with a psychotic disorder would describe this as critical comments, overt or subtle hostility, or emotional overinvolvement in the individual's affairs.
<i>Independent life event</i>	A life event or situation that is not related to an individual's psychotic symptoms and is beyond his or her personal influence, for example, the death of a relative, the loss of a job because the entire company went out of business, or becoming the victim of an unprovoked attack.
<i>Mediator</i>	A variable that explains how, why, or when to expect a relationship between a predictor (e.g., life event) and the criterion (e.g., psychosis).
<i>Prospective studies</i>	Research in which the data are collected on an ongoing regular basis about all study participants, whether they are considered at risk for an illness or not and before the event being studied occurs (e.g., psychotic relapse).

Protective factor

Individual characteristics, which may be biological, intrapersonal, interpersonal, or learned, that reduce or eliminate the risk of developing a psychosis.

Stress

An adverse biological, physiological, or psychological state that develops when the demands on an individual exceed his or her capacity for adaptation.

Vulnerability to psychosis

The enduring characteristics of individuals, which might be genetic, social, behavioral, biochemical, cognitive, or related to brain structure, that increase their susceptibility to developing psychosis.

Stress is a concept on whose definition few scholars or researchers can agree. Yet there is little dispute that stressful events can influence the onset and course of major psychotic disorders. A 1977 vulnerability–stress model by Zubin and Spring proposes that a relationship exists among the level of inherited vulnerability, stress that exceeds a certain threshold, and the onset or relapse of psychotic illness. According to this vulnerability model, individuals with high biological vulnerability are susceptible to the exacerbation of psychotic symptoms even when they experience low levels of stress; however, if the biological vulnerability is low, then high levels of stress are required before symptoms emerge. Differences in the rates of psychotic disorders found in males versus females, urban versus rural areas, and high-stress versus low-stress households support the importance of environmental factors in understanding gene–environment interactions.

Several empirical tests of the vulnerability–stress model have shown that an increase in the frequency of life events occurs in the month before a psychotic exacerbation. However, not all studies have found a reliable association between stressful life events and psychosis. Some researchers believe that the relationship in schizophrenia is weak when compared to more striking findings in patients with mood disorders. Although there is a convergence of evidence that stressful life events are triggers of psychosis, stressful events alone are neither necessary nor sufficient to account for illness onset, nor are they necessary as precursors of relapse. Antipsychotic medication may provide protection against stress and raise the threshold of vulnerability. An interactive vulnerability–stress–protective factors model (Figure 1) hypothesizes the existence of mediators of stress, some of which are considered protective such as

Figure 1 An interactive vulnerability–stress–protective factors model of risk factors for the onset and course of psychotic disorders.

cognitive appraisal of life events, social competence, social and familial support, and premorbid intelligence.

Stress in Psychotic Disorders: Conceptual Framework

All biomedical disorders, including those that manifest themselves by psychotic symptoms, are stress-related biological illnesses. It doesn't matter whether it is the heart or the brain that is involved as the organ from which the illness arises, stressors impinge on the organ's genetic vulnerability to trigger episodes of symptoms, exacerbations, relapses, and disability. Moreover, protective factors in the individual or in the individual's environment can mitigate or buffer the noxious effects of stressors on vulnerable people. When protective factors – such as social competence, social and family support, intelligence, availability, and accessibility to preventive interventions and good quality treatment – outweigh stressors and vulnerability, health may be sustained and disability forestalled.

In this article, we identify some of the stressors that have been implicated in the induction of episodes of illness, relapse, and poor outcome in psychotic disorders. However, it is important to place the role of

stressors within the framework of the vulnerability–stress–protective factors model so as to understand why an individual may experience an episode of illness when exposed to a stressor at one time but not when exposed to the same stressor at another time. In addition, the vulnerability–stress protective–factors framework permits clinical scientists to explain the enormous interindividual variability in susceptibility to stressors – in short, why some people, some of the time, do not experience stress and exacerbations of psychosis in response to certain stressors, but others do.

Stressful Life Events and Psychosis

The life charts of Adolf Meyer, published in 1951, were among the first records of clinical observations that emphasized the importance of psychosocial stressors and the development of pathological conditions. Over the past 3 decades, many researchers have attempted to empirically document the nature of the relationship between stressful life events and psychotic illness. Such studies are based on the notion that higher frequencies of events translate into higher levels of stress for patients. These studies can be grouped into those that compared schizophrenia patients and other psychiatric groups, those that

compared schizophrenia patients with community controls, and those that examined the impact of stressful events on the onset and relapse of psychotic symptoms.

Most research has shown that, compared to schizophrenia patients, other psychiatric groups (usually depressed patients) reported either similar or significantly higher rates of stressful events prior to an episode. These differences were unexpected because there was an assumption that the rate of stressful life events in schizophrenia patients was higher than for patients with other psychiatric disorders. Schizophrenia patients are considered sensitive to even subtle changes in the environment. However, given that schizophrenia patients sometimes withdraw when stressed, their rate of life events may actually be lower than the rate for patients with other psychiatric disorders. Available evidence supports the conclusion that schizophrenia patients report fewer life events than other diagnostic groups. Furthermore, most studies have found that the strength of the relationship between stress and symptoms is more robust in patients with major depression than in patients with schizophrenia.

Most studies that used community controls as a comparison found that schizophrenia patients experienced a higher frequency of stressful events. However, some studies showed no difference. Interestingly, one prospective study found that normal controls actually had higher levels of stressful events than did schizophrenia patients. Several studies have shown an increased frequency of triggering life events in the month prior to the onset or relapse of schizophrenic symptoms. Even studies that did not find a sharp increase in the number of life events in the month prior to onset or relapse found that stressful life events had increased the risk of psychosis. There has been some investigation into whether life events play a more prominent role in the onset of psychosis than in relapse. Although there is no consistent evidence favoring a relationship between stress and onset (compared with stress and relapse), there is some indication that life events play a larger role in psychotic episodes that have a discrete (vs. insidious) onset.

Perhaps more relevant than the absolute frequency of events in patients or controls is the nature of the relationship between life events and psychotic illness. However, most of the studies of stress and psychosis focused on the frequency of events rather than the amount of threat posed. In fact, methods of measuring life event frequency (through open-ended interviews or life event inventories) are readily available. But, in some cases, events that were hoped for or expected (e.g., finding a suitable mate) but did not

occur may also be perceived as stressful. Most researchers believe that the impact of a stressor is determined by an individual's cognitive appraisal and that the appraisal is altered in schizophrenia patients in a way that increases vulnerability to stress and psychosis; yet this important topic has received limited study. Perhaps the popular belief that most schizophrenia patients cannot accurately report their appraisal of life events dampens researchers' enthusiasm for comprehensive study.

Retrospective Studies of Life Events and Psychosis

In a classic and frequently cited 1968 British study, Brown and Birley interviewed schizophrenia patients and their families soon after a hospitalization regarding the 12-week period prior to the onset or relapse of psychosis. Schizophrenic patients reported an increased frequency of independent life events (independent of the insidious onset or occurrence of psychotic symptoms) in the 3-week period prior to the datable onset of their episode. Specifically, 46% of patients reported an independent life event in that 3-week period, compared with 14% for a sample of community controls during a comparable period. Except for the 3-week period prior to an episode, the life event rates between the two groups did not differ significantly. From these results, Brown and Birley concluded that life events play a role in triggering the onset or relapse of psychotic symptoms in schizophrenia.

The most ambitious attempt at a replication of the Brown and Birley findings was a 1987 multinational World Health Organization (WHO) study published by Richard Day and colleagues. The design of this WHO study was virtually identical to Brown and Birley's original work, including the use of retrospective reporting, although normal controls were not included. The life events data were collected in nine centers, five located in developed countries and four in developing countries. Day and colleagues replicated the finding that independent life events occur with increased frequency in the 3 weeks prior to psychotic episodes in schizophrenic patients. Although the lack of a comparison group is a serious concern, the consistency of these findings from different countries lends considerable support to the hypothesis that stressful life events may trigger episodes of schizophrenia.

Questions Concerning Retrospective Studies

Most of the classic research supporting the idea that stress triggers psychosis has been subject to criticism because the data was collected using retrospective methods, in which data regarding life events were

collected after onset or relapse of psychosis. Because retrospective data gathering relies on the patient's memory of life events and the date of onset of psychotic symptoms, it is subject to considerable report distortion, particularly for events of smaller magnitude. Such distortion is likely to bias results when patients (or their families) are searching for an explanation for a known outcome, such as a psychotic episode. In addition, there is the issue of bias in the dating of the onset or relapse of psychosis in these studies. Such a bias favors finding a relationship between stress and psychosis even if there was none.

The prospective studies of the mid-1980s and 1990s, which used a follow-through design in the regular collection of life events data, were aimed at correcting the methodological flaws of the prior retrospective studies. In some studies, life events data were collected as often as biweekly, thereby minimizing errors associated with memory for stressors that preceded relapse. In addition, each patient's symptoms were assessed frequently, minimizing the distortion of an association between the presence of symptoms and certain events.

Prospective Studies of Life Events and Relapse

The first well-designed prospective study of schizophrenia outpatients addressed the question of whether a significant increase in symptoms occurs after independent life events rather than evaluating the frequency of life events in the month preceding symptom relapse. This study, which collected life events data on an ongoing regular basis, focused on the average effects of life events on illness. An increase in negative symptoms was found in response to stressful events but not an increase in positive psychotic symptoms. Based on this stringent test of the relationship between stress and psychosis, Jean Hardesty and colleagues concluded that independent life events have minimal bearing on florid psychotic symptoms in schizophrenia.

A 1989 prospective study by Ventura and colleagues introduced additional methodological improvements in data collection, including (1) careful monitoring of the amount of antipsychotic medication received, (2) the use of both an open-ended style of interviewing and a structured life events inventory, and (3) the classification of life events as independent only when they were both independent of the patient's illness and not within the patient's ability to influence them. Ventura et al. found, as had Brown and Birley, and Day and colleagues, an increase in the number of independent life events in the 4-week period before a relapse or significant exacerbation of positive symptoms; 5 of 11 (45%) patients had at least one independent life

event in the month before relapsing, compared with 1 of 11 (9%) during a comparable period without relapse. Thus, a well-designed prospective study supported the conclusion that stressful life events play a role in triggering psychotic symptoms.

Stress Sensitivity

Researchers and clinicians alike have theorized that schizophrenia patients are sensitive to even very small negative changes in the environment. A series of studies using the Experience Sampling Method (ESM) has provided some evidence for the validity of this hypothesis. The ESM requires that patients wear a beeping watch that alerts them 10 times a day to record real-life activity and their emotional response over a 6-day period. Using the ESM, researchers in the Netherlands found that schizophrenia patients, compared to high-risk relatives and controls, are more likely to experience negative affect in response to minor life events. This negative affectivity is considered a vulnerability marker for future psychosis. In addition, using the ESM the researchers recorded life events in sets of twins, in which one twin scored high on a measure of psychosis proneness and the other scored low. The advantage of this method of research is that the well twin acts as a genetic control for the psychosis-prone twin. Twins who were prone to experiencing psychotic-like experiences were more likely to show sensitivity to minor stressful life events. These findings further support the hypothesis that stress sensitivity acts as a risk factor for psychosis.

General Conclusions on Life Events and Psychosis

Interestingly, similar conclusions about the relationship between stress and psychosis can be drawn from sophisticated prospective studies and the retrospective studies. There is strong evidence from both retrospective and prospective studies to support the triggering hypothesis, even though some studies were able to confirm only an increased risk of psychosis from stressful events. Although life events influence psychotic episodes, the occurrence of stressful life events is usually not sufficient to precipitate an increase in psychotic symptoms. Furthermore, life events are not always necessary for relapse to occur. Some studies found that more than one-half of relapsing patients did not experience a prior life event. Other factors, such as medication reduction/discontinuation or biological factors, may also contribute to the risk of relapse. These conclusions attest to the potential importance of mediators such as, cognitive appraisal and coping efforts, which produce

differences in individual response to stress within groups of psychotic patients. The finding of increased negative symptoms in response to stressful events, instead of psychosis, indicates that not all patients respond to stress in the same way. Prospective research has also shown that life events do not have to be large in magnitude; both major and minor life events are predictors of symptom exacerbation and relapse in schizophrenia. Furthermore, stress sensitivity to daily hassles and minor life events has been associated with increased subjective distress and potential risk for future psychosis in schizophrenia.

Cognitive Appraisal of Stressful Events

Understanding the link between stressors and subsequent psychotic symptoms in schizophrenia may entail looking more closely at potential mediators such as patients' cognitive appraisal of life events. According to stress researchers, an individual's appraisal of an event always should be measured because appraisal determines the stressful nature of the event. In one stress-illness model, the perception of the stressor is schematically represented as a polarizing filter that can magnify or diminish the stressfulness of an event. Richard Lazarus and Susan Folkman hypothesized that appraisal is the first element of a two-phase cognitive-phenomenological process of coping and thereby is a factor in determining how much stress an individual experiences. After decades of research, Lazarus continued to assert that an individual's appraisal is necessary and sufficient in the generation of emotions in response to stressful events. Appraisal thus is relevant to understanding the relationship between stressful life events and subsequent illness.

Research suggests that schizophrenic patients, in particular, might respond in idiosyncratic ways to life events. Appraisal may play a larger mediating role in the relationship between life events and psychotic symptoms in schizophrenia patients than it does in other populations. Both psychoanalytic and cognitive information-processing theories suggest that schizophrenia patients rely on narrow and idiosyncratic meanings of events. Heightened sensitivity to environmental stimuli, coupled with cognitive distortions and psychotic thinking (e.g., persecutory ideas or referential thoughts to either perceived or existing threats) could result in increased stress. Research has shown that schizophrenia patients may overestimate the threatening nature of everyday events or situations and underestimate the effectiveness of their problem-solving ability. This tendency for altered appraisal may increase in patients as their condition worsens.

Can Stress Cause Psychotic Illness?

Although some investigators have argued that stressful life events can cause psychotic episodes in schizophrenia patients, others have argued that life events can only act as triggers of episodes. Central to this issue is whether psychosis can occur in individuals without inherited vulnerability and from stressful events that are definitely independent of the illness. Exposure to wartime combat, natural disasters, and other severe traumatic events that are clearly independent of the individual's influence have been shown to increase the risk of developing psychosis. According to one theory, psychosis can occur even in individuals without inherited vulnerability characteristics, especially if the stressor is severe. However, many individuals have been exposed to all types of stressful situations and catastrophic events and only a handful become psychotic. Some theorists believe that individuals who became psychotic must have some type of underlying vulnerability to illness and that therefore the stress merely acted as a trigger. The possibility also exists that the role of life events may be indirect and occur in conjunction with other risk factors.

Stressful Life Events and Depression in Psychosis

The presence of clinical depression in schizophrenia patients has generated a great deal of interest because of its significance as an early indicator of an impending psychotic relapse, association with an increased risk for suicide attempts, and relationship to psychiatric rehospitalization. Several theories have been put forward to explain the occurrence of depression in schizophrenia. Depression has been considered part of the postpsychotic phase when it occurs after a psychosis remits and as a reaction to the realization that the individual is in trouble or that his or her life has fallen far short of prior expectations. Other researchers view depressive symptoms as part of the acute psychotic process because it has been found to occur simultaneously with the exacerbations of positive symptoms. Depression may be a part of the patient's biological diathesis to schizophrenia and therefore an integral part of the disorder or an aspect of familial genetic liability to disturbances in mood. Some researchers view depression as an unwanted side effect of antipsychotic medication. However, observations by Eugen Bleuler and Emil Kraepelin of depression in schizophrenia during the preneuroleptic era suggest that depression is not simply secondary to antipsychotic medications. In any event, according to the vulnerability-stress-protective factors model, psychosocial stressors such as life events may be expected to increase the chances

of an onset or exacerbation of depressive symptoms in psychotic patients.

Schizophrenia patients have reported a higher frequency of stressful life events during the 6 months before a depressive exacerbation and during the 12-month period prior to a postpsychotic depression. Early parental loss (before age 17) was also found to be more common in depressed than nondepressed chronic paranoid schizophrenia patients. In chronic schizophrenia patients, increased levels of depression have been found to be associated with psychosocial stressors, such as unemployment. Although much of this previous research had some methodological weaknesses, recent work with sound methods confirmed the earlier findings. A well-designed 2000 prospective study using survival analysis showed that stressful life events act as triggers of depressive exacerbation in recent-onset schizophrenia patients. These studies suggest that individuals with schizophrenia who experience undesirable life events may have a vulnerability to depression similar to mood disorder patients and individuals without psychiatric disorders. Thus, stressful events may play an even broader role in psychosis than is typically theorized by the vulnerability–stress–protective factors model.

Natural Disasters and Psychotic Disorders

There are various types of stressful life events that can have a negative impact on schizophrenia patients, ranging from minor daily hassles to major life events. These include catastrophic events such as natural disasters. One reliable predictor of psychiatric morbidity is the degree of exposure to the devastating physical consequences that follow natural disasters. Research on natural disasters showed consistently that the existence of a prior psychiatric disorder (or symptoms) is a risk factor for postdisaster psychopathology. Preexisting disorders such as major depression, posttraumatic stress disorder (PTSD), anxiety disorders, and alcohol dependence have been associated with postdisaster morbidity. One study found 98% of individuals with a prior psychiatric disorder had a diagnosable postdisaster psychiatric disorder, compared with 25% of postdisaster diagnosis in the group without a previous diagnosis. Most studies have been retrospective and therefore subject to recall bias, but these results have been supported in prospective research.

Contrary to what is predicted by the vulnerability–stress–protective factors model, most anecdotal accounts and a few studies indicated that psychiatric patients remain clinically stable or even improve during or after natural or human-made disasters

(e.g., hurricanes, ice storms, nuclear power plant accidents, and missile attacks). During Hurricane Iniki, psychiatric inpatients in Hawaii responded with increased independence, defined as decreased requests for therapy. Similarly, during SCUD missile attacks on Israel throughout the Persian Gulf War, many psychiatric inpatients were described as having coped well, quietly entering sealed concrete bunkers and easily donning gas masks. During a state hospital fire, the patients assisted the hospital staff in the efforts to control the blaze.

In contrast to these prior reports, patients with psychotic disorders in some studies of disasters demonstrated evidence of heightened stress reactivity. On January 17, 1994, a 6.8-magnitude earthquake struck Northridge, California, and provided our research group with an unprecedented opportunity to study the impact of a natural disaster on psychotic patients. Our sample consisted of patients who were previously diagnosed as having a psychotic disorder and were active participants in research projects. As hypothesized, the degree of exposure to the earthquake was a statistically significant predictor of the amount of distress experienced. Schizophrenia patients reported higher levels of avoidance symptoms than did controls when assessed postearthquake. However, the groups did not significantly differ in their mean levels of intrusion symptoms. The specific elevation of avoidance symptoms is noteworthy because the early appearance of avoidance and emotional numbing has been found to be the strongest predictors of disaster-induced psychiatric morbidity, including PTSD. BPRS assessments were compared for patients for whom 1-week preearthquake and 1-week postearthquake ratings were available. We found a significant increase in postearthquake dysphoria but not in psychotic symptoms. In response to the September 11, 2001, terrorist attacks, there was no difference between inpatients in New York who did and inpatients who did not have the opportunity to directly view the disaster through downtown-facing windows. However, patients with a schizophrenia spectrum diagnosis showed evidence of worsening symptoms compared to those with affective disorder or other diagnoses. Although there is some evidence of confirmation of the stress reactivity hypothesis in response to disasters, the stress reactions of psychotic patients are not always consistent and might depend on the amount of exposure, type of disaster, and the setting.

Expressed Emotion as a Stressor

High expressed emotion (EE), the attitudes and feelings expressed by a family member to a patient with a

psychotic disorder, is the most potent stressor precipitating relapses. EE is a misnomer because it does not refer to emotional expressiveness but, rather, to very specific and operationalized types of attitudes and feelings that are associated with stressful interactions within a family living with a severely mentally ill person. These attitudes and feelings take the form of critical comments, hostility, and emotional overinvolvement. Critical comments are complaints about specific behaviors or symptoms of the mentally ill family member, whereas hostility is generally directed at broader and more global personality characteristics. Emotional overinvolvement is overprotectiveness, intrusiveness, self-sacrificing behavior, and hovering over the patient by the family member. Conversely, low EE, which is associated with lower than average relapse rates, may subserve a protective function by insulating the individual from stressors with positive comments, positive reinforcement, and warmth.

Family members' levels of EE are reliably associated with patients' risks of relapse in the subsequent 9–12 months after a psychotic episode. Patients living with or having frequent contact with one or more high EE relatives have relapse rates 2–3 times greater than patients living with or having contact only with low EE relatives. This increased risk is present despite adequate treatment with antipsychotic medication. In a recent meta-analysis of 27 studies, the average rate of psychotic relapse in patients living with one or more high EE relatives was 52%, compared to 22% in patients coming from low EE families. The probability that this result was due to chance is virtually zero. This association of EE and relapse has been found for relapses in bipolar disorder, schizophrenia, and major depression.

Although there is no evidence whatsoever that EE or families have an etiological role in the first episode or development of psychosis, there is solid evidence that there is a causal link between EE and relapse. More than 15 treatment studies in several countries have shown that behavioral, social learning, and psychoeducational interventions that are well-organized, structured, and focused on teaching family members practical methods for understanding and coping with psychosis lead to reductions in EE and in relapses. Thus, the treatment research provides experimental evidence for the role of EE in stress-related relapse.

The association between EE and relapse in psychosis has been consistently found in developing countries (e.g., India) and developed countries (e.g., United States, United Kingdom, and Italy); however, cultural factors do play a role in the proportion of families from various cultures who are high versus low EE. For example, the proportion of high EE

families is significantly lower in rural India than in urban India and is lower among unacculturated Mexican American families than among Anglo-American families. It is likely that cultural factors play a role in the way that families react to and cope with major mental illness in a relative, and this moves the understanding of EE into an interactional framework.

During direct observation of high EE family members interacting to solve a problem, the emergence of subclinical psychopathology in the patient triggered responses by the patient's relatives that might be viewed as incipient signs of high EE. Negative interactional cycles escalated, with efforts by the family to squelch the patient's deviant behavior, leading to more intense symptomatic behavior and greater negativity in the cycles. There is evidence also that enduring personality, attributional, and information processing factors in high EE relatives may contribute to the association between EE and relapses in psychotic disorders. For example, families who perceive the causes of the patients' problems or symptoms as being controllable by the patients (i.e., families with high internal locus of control) are more likely to be high EE. On the other hand, families that are rated as having higher tolerance, flexibility, empathy, and communication are more likely to be low EE.

The role of EE as a stressor in schizophrenia and other psychotic conditions is elucidated by the stress-vulnerability-protective factors model. Certain characteristics of relatives (e.g., attributional style) may predispose them to experience stress when they are faced with abnormal, unpredictable, and even dangerous behavior in their ill family member. They attempt to cope with this stress by using any means at hand – even criticism, hostility, or emotional overinvolvement – and this has counterproductive effects on the ill relative, causing that person stress and leading eventually to relapse after many cycles of stress superimposed on vulnerability in both the patient and relatives. The interactional nature of EE that develops in this synchronous fashion does indeed link stress, vulnerability, and protective factors in both the family members and patient.

Treatment as Protection against Stress and Psychosis

The Role of Antipsychotic Medication in Reducing Psychosis

In most, if not all studies, antipsychotic medications have repeatedly been shown to be effective for the treatment of psychosis and the prevention of relapse in schizophrenia. Brown and Birley reported that a

larger percentage of patients who relapsed while taking an antipsychotic medication had experienced a life event compared to patients who relapsed while not on medication. Additional work by Brown and Birley in 1968 also suggested that “life events and reducing or stopping phenothiazines [antipsychotic medication] contribute as precipitants of acute schizophrenia.” Similar results were published showing that a significantly greater proportion of the patients who relapsed on medication had experienced an independent life event, compared to nonrelapsing patients not on active medication. Leff proposed that regular antipsychotic maintenance medication produces a prophylactic effect against stress by raising a patient’s threshold to relapse; this increased threshold makes the patient less likely to relapse unless exposed to major life stressors.

In a 1992 prospective study, Ventura et al. found that patients who had a psychotic exacerbation while on medication had more independent events in the prior month than did patients who had an exacerbation while off medication. As previously proposed by Leff, Ventura et al. concluded that taking an antipsychotic medication is protective and raises the threshold for relapse. However, another well-designed study did not completely support the hypothesis that life events are more relevant to relapse in patients on maintenance medication.

Behavioral Family Management for Reducing Stress Inherent in High Expressed Emotion

As shown in [Figure 2](#), the daily hassles and challenging or stressful events of everyday life in a family with a relative who has a disabling psychosis can be dealt with in either of two ways. If the family is equipped with good coping and communication skills, these daily problems can be decompressed and solved without the emotional temperature in the family rising above the ill relative’s vulnerability threshold, decreasing the risk of relapse. However, families that lack the know-how and skills to cope with the stressors of everyday life can, all too readily, succumb to a cycle of stress, poor communication, and mounting problems, leading to relapse. Given the large proportion of families that show high EE in the United States and most developed countries, an intervention program is essential to cool the family emotional temperature.

Behavioral family management, initially designed by Liberman, Falloon, and their colleagues at the UCLA Center for Research on Treatment and Rehabilitation of Psychosis, comprises education of the family and patient about the nature of the mental illness affecting the patient, information and advice about using community-based resources for treatment and rehabilitation, planned and structured

Figure 2 Role of the family in preventing relapse.

training in communication skills, and training in problem solving. Research conducted and replicated on behavioral family management and related treatments has revealed that family-based stress management and skills training is a highly effective addition to the long-term clinical management of psychotic disorders. This modality of treatment has shown superiority in reducing relapse and rehospitalization rates, improving rates of remission of symptoms, enhancing social outcomes, and increasing family and economic benefits. Moreover, the technique can be adapted to be useful in a wide variety of settings, employed by many different disciplines of mental health workers, and effective in a spectrum of patient populations.

Coping with Stressful Life Events

Stressful life events occur often enough in the lives of schizophrenia patients to significantly increase the risk of psychotic relapse. Some research suggested that individuals who experience stress, but who do not relapse, possess psychological characteristics and cognitive functioning that may be associated with effective coping. In particular, the use of problem-focused coping strategies has been associated with good neurocognitive functioning and has been shown to lessen the impact of stressful life events by lowering the risk of relapse. High levels of self-esteem, hope, and insight and the perception of available social support were found in schizophrenia patients who reported using active problem-focused coping strategies. Protective mechanisms, such as effective coping behaviors, in patients and their families may have changed stressful situations into more minor events and reduced the risk of relapse. Positive symptoms have been reduced in patients who consistently applied coping strategies to stressful life events and used problem-solving techniques. These findings support the importance of coping behavior as a protective factor and mediator in the vulnerability–stress–protective factors model.

Despite good evidence for the value of using specific problem-focused coping strategies, schizophrenia patients may fail to use them. This differential use of coping strategies may explain the variability of schizophrenia patients' responses to stressful events. Even after training, they may continue to use ineffective strategies and report that the strategies they used most often were the least effective. Despite the fact that successful coping behaviors may be protective and can be learned, relatively few patients seem to avail themselves of the benefits of using coping strategies. In addition, because many schizophrenia patients have aversive reactions to stressful events, they may respond with avoidance and withdrawal to reduce their acute stress. Thus, further longitudinal research is needed to determine whether short-term or brief avoidance could in some way be adaptive or always leads to problems later.

The Concept of Quality of Life

Assessment of Quality of Life

Dimensions of Quality of Life

Glossary

<i>Subjective</i>	Personal.
<i>Objective</i>	Detached from personal views.
<i>Observable</i>	Visible.
<i>Perceptions</i>	Views.
<i>Functioning</i>	What a person is capable of doing.
<i>Encephalograph (EEG)</i>	Measured electrical changes in brain waves.
<i>Eustress</i>	Positive or “good” stress.

The Concept of Quality of Life

Quality of life (QoL) has become a key goal of contemporary health care. It is often confused with standard-of-living. However, standard-of-living refers to the possession of wealth or material goods. Although a certain number of square feet of living space in United States, or oxen owned in Ethiopia, makes a tangible difference in people's lives, it does not necessarily bring greater happiness or well-being; we can observe this in lottery winners. International figures on annual income per capita collected by the World Bank show that once income exceeds a critical level – \$13,000 in 1995 – the close relationship between subjective well-being and income becomes increasingly loose and dissipated. Furthermore, in the world's richest countries standard-of-living increases do not appear to make a significant difference to people's QoL, a finding that is highly perplexing for policy makers.

A consensus about how to define and measure QoL is still widely debated. In the 1970s, its definitions contained terminological similarities to definitions of

stress. At a time when stress was seen as a phenomenon that exceeded people's resources, in order to provide a good QoL these resources needed to be adequate in terms of satisfying people's wants, needs, and capacities. Since then, definitions have placed greater emphasis on people's subjective perceptions of the important features of their life and, in particular, explored the varied meanings ascribed to these experiences. The ways in which people interpret life's events (e.g., as stressful or pleasant) affects how they see their QoL. Wenger et al. (1984) defined QoL as “an individual's perceptions of his or her functioning and well-being in different domains of life.” Judgments about QoL are now seen as a rich interplay and balance between how people see their internal state, such as the tension in muscles or happiness, and the external events that impinge on them from their environment, such as changing jobs or being bereaved.

Assessment of Quality of Life

The history of QoL assessment measures shows that some of the earliest versions were designed by clinicians for their own use in distributing health-care resources, for example the assessment of Quality Adjusted Life Years (QALYS). This approach excluded a systematic assessment of patients' views, with the assumption that clinicians held a reasonably accurate view of their patients' QoL. However, research has consistently shown that QoL judgments by clinicians and other observers (e.g., spouses or caregivers) often correlate weakly with the views held by the patients about their own QoL. Such proxy information is therefore unreliable, and this is particularly apparent in the case of dementia or stroke, in which the patients' own perceptions can be difficult or impossible to obtain. This discrepancy arises from the observation that many aspects of QoL are simply not open to inspection but are hidden from view like the submerged parts of an iceberg. Furthermore, when measures have limited their contents to subjective reports of observable behaviors such as mobility and

activities of daily living, it has resulted in the assessment of a constricted rather than holistic concept of QoL, due to the exclusion of important but invisible QoL issues such as spirituality and social relationships.

The need for QoL assessment in health has been driven by the problem-solving demands of clinical practice. The aim was to better understand the patient's priorities in order to deliver appropriate care. However, this approach may have provided an unduly negative view of QoL. Patients expect to report their problems during a consultation and to do this succinctly. In these time-limited conditions, they are unlikely to also discuss the positive qualities of life such as the pleasure they get from playing with children, listening to Mozart, or seeing a dewdrop on a leaf. Consequently, many measures have tended to focus on assessing symptoms and dysfunctional aspects of life to the exclusion of the good life. This not only gives health professionals the view that the QoL of their patients is worse than it is, but it also causes the patients who complete the questionnaire to report feeling miserable after focusing unduly on the bad things instead of a more balanced life. Even highly disabled, chronic-pain patients entering a pain management program after many surgical and pharmacological treatments report that chronic pain affects only half the important qualities of life when a range of positive and negative issues are presented for evaluation. The good life was acknowledged by Aristotle and several eighteenth-century philosophers, but has only recently been endorsed again as pertinent to outcomes measurements in health care. Hence, more recent definitions of QoL have sought to emphasize a positive orientation: "The essential characteristics of life, which in the general public is often interpreted as the positive values of life, or the good parts of life, or the total existence of an individual, group or society" (Lindstrom, 1992).

The Example of Sleep as a Quality of Life

Another debate concerns the type of information that constitutes the best measure of QoL, and here sleep provides a suitable example. Researchers have assessed sleep-related QoL by tracing electroencephalograph (EEG) waves, considering this to be an objective indicator. Others assess the timing of sleep and wakening, insomnia patterns, medication use, and so forth, in looking at people's objective perceptions of their sleep. However, we can argue that information derived from either of these channels of inquiry tells us only indirectly about people's QoL. These types of information require further interpretation by the researchers, and their own assumptions may lead

them to draw an erroneous conclusion. Would the people you know see your QoL as good or bad if you told them you slept 3 h a night? What about 12 h a night? Without additional information about whether that sleep was refreshing, it is not possible to draw an accurate conclusion. For this reason the most reliable way to avoid this pitfall is to ask subjective QoL questions such as whether people find their sleep to be refreshing or not. Conclusions about these qualities cannot, therefore, be deduced; direct questioning about the meaning of events is required. Like stressful life events (e.g., divorce), it is the interpretation that matters. Although all these three types of information are themselves valuable and can be used together to form a fuller picture, we contend that QoL is best measured as a subjective phenomenon and that the use of the term should be restricted to this type of information.

The World Health Organisation Definition

Questions have been raised about whether QoL is a global phenomenon or just a Western concept. Although culture has sometimes been included in QoL models, it is usually seen as extraneous and additional, rather than taking a central role in explaining the diverse ways in which different cultural groups interpret QoL. Concerned to understand QoL relating to global health, the World Health Organisation views culture as a "lens" through which people interpret the experiences that affect their QoL. It defines QoL as "an individual's perception of their position in life, in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards, and concerns" (World Health Organisation Quality of Life Group, 1994: 43). This unusual definition also implies that comparisons are used in helping to make decisions about QoL; that in evaluating their own QoL, people consider how far they have achieved their goals, expectations, and standards, in addition to considering problematic concerns.

Dimensions of Quality of Life

So what does a good QoL consist of, and is there consensus about whether these dimensions are universal? Many hundreds of QoL questionnaires have included the two broad components of physical and mental health identified by Descartes as essential. However, physical health is operationalized in some assessments in terms of symptoms; adding symptoms does not give a clear view of people's QoL because, paradoxically, patients with many symptoms often report a relatively good QoL and, conversely, those

with very few symptoms report it to be poor. Measures also often include estimates of independence or functional status, such as mobility, activities of daily living, and so on. Physicians have traditionally favored those QoL dimensions for which they can independently inspect corroborating evidence alongside the subjective reports. Some issues such as spirituality have largely been ignored as being too difficult to measure and/or irrelevant to health and health care.

The universality of QoL and its dimensions have been addressed by the World Health Organisation Quality of Life (WHOQOL) Group, which has confirmed that physical, psychological, independence, social relations, environmental and spiritual dimensions are important in a wide range of cultures and settings and to sick and well people. Within these broad domains, the group confirms 25 detailed aspects (facets) of QoL that are reliable and valid internationally. A series of novel procedures was used by the WHOQOL Group to create several multilingual instruments and a short version – the WHOQOL-Bref – is now available in over 50 different languages. In addition to the main measures, add-on modules of extra questions have recently become available to support work on spirituality, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), older adults, and pain. The WHOQOL results provide support for the view that there is broad recognition and universal agreement about a concept called QoL, even though it may not be labeled as such, and that there are cultural variations in the relative importance of the dimensions included, as well as in how these issues themselves are expressed.

Uses of Quality of Life Assessments

QoL assessments are used for monitoring outcomes (e.g., after policy change). In particular, they are valued widely as a suitable outcome measure in randomized controlled clinical trials. Although outcomes are the main focus here, it is worth noting that QoL can also be investigated as a process. Because psychometric measures are designed to tap into outcomes, the results from these instruments provide merely a snapshot of QoL at one time in an ever-adjusting process. Different theories and techniques may be needed to investigate how and when QoL changes over time and precisely which factors (e.g., stress and eustress) affect positive and negative changes.

Introduction: Discrimination Persists

Discrimination and Racial Harassment

Several lines of evidence converge to suggest that discrimination is an important feature of life in race-conscious societies in which race is an important determinant of access to a broad range of societal benefits and rewards. First, social psychological theory identifies discrimination as a key aspect of intergroup relationships that serve to reinforce the symbolic boundaries that separate one social group from another. Second, there is broad recognition that discrimination persists for socially disadvantaged populations. The American public acknowledges that a high level of discrimination and prejudice exists. National public opinion data reveal that most Americans concede that racial minorities suffer from a fairly high level of racial bias. Blacks are perceived as experiencing the most discrimination, followed by Hispanics and American Indians, and then Asians. They also perceive that some White ethnic/religious groups such as Jews, Italians, and Catholics experience more discrimination than Whites in general. In one national study, for example, two-thirds of the American population reported that blacks suffer a lot or a tremendous amount of discrimination.

Some of the best evidence of the persistence of discrimination comes from audit studies in which

carefully matched Black and White applicants with identical qualifications apply for jobs or housing. Audit studies in employment, for example, find that discrimination favors the White over a Black applicant in one in five audits. Other audit studies suggest that discrimination persists for Blacks and other minorities in the purchase of a broad range of goods and services. For example, one carefully executed study found racial differences in the best price offered for the purchase of a new car. In this study, Black and White testers were sent to automobile dealerships to negotiate the price of a new car. Although all the testers were carefully trained to follow the same script, there were large racial and gender differences in the final price offered for the new car, with White males offered the lowest prices, followed by White females, African American males, and African American females. Similarly, a recent report from the Institute of Medicine documented systematic and pervasive discrimination in the quality and intensity of medical treatment received by Blacks and other minorities in the United States. Thus, there is abundant evidence that discrimination persists in contemporary society. However, not all experiences of discrimination are visible to their intended target. Frequently, victims of discrimination lack all of the details about an interpersonal transaction that they need to know in order to establish that discrimination has occurred. Although self-reports of bias understate the full extent of exposure to discrimination, they capture an important part of discriminatory experiences that are likely to be consequential for health.

Discrimination as a Stressor

This article focuses on aspects of discrimination that are perceived by individuals in society. Subjective experiences of discrimination or unfair treatment are viewed as an important type of stressful life experience that many traditional measures of stress fail to assess. Equity theory suggests that perceptions of unfair treatment can lead to negative emotional reactions and psychosomatic symptoms. Discrimination

can also be stressful because it can reinforce negative social stigma and highlight low social regard. Qualitative descriptions of experiences of discrimination indicate that they can induce considerable levels of psychological distress. Laboratory studies have examined the experimental manipulation of unfair treatment and have found that it leads to elevated levels of psychological distress for a broad range of social groups. Other studies have directly measured physiological responses to racially stressful material in the laboratory setting. These studies have used mental imagery and videotaped vignettes of discriminatory behavior. Most, but not all, of these studies have found that exposure to discrimination leads to cardiovascular and psychological reactivity. An important methodological strength of laboratory studies is that they do not rely on respondents' self-reports of discrimination. However, observed effects in the laboratory are short term, making the extent to which acute physiological arousal under laboratory conditions generalizes to chronic elevation of stress processes and mechanisms in real life unclear. Some recent research documents that high reactivity to acute stressors in laboratory settings is predictive of elevated rates of hypertension several years later. Most of the early laboratory studies focused on Blacks. It is not clear from these studies, however, whether the physiological reactivity to racism-linked experiences is unique or enhanced in comparison to reactivity to other types of stressors.

Studies of Discrimination and Health

Mental health status is the most frequently used health measure in studies of discrimination. Multiple mental health indicators have been used. These include measures of well-being, self-esteem, perceptions of control, psychological distress, anger, and specific psychiatric disorders such as major depression, generalized anxiety, and substance use. These studies have found an inverse relationship between discrimination and mental health – higher levels of discrimination were associated with poorer mental health status. Most of the early research studies in this area were based in the United States and tended to focus on African Americans. Recent studies have documented similar patterns of associations for other minority groups in the United States. For example, studies of Mexican Americans, Chinese Americans, and American Indians have found that perceived discrimination is associated with higher levels of psychological distress. A growing number of international studies documented similar patterns. Studies of Asian immigrants in Canada; Iranians, Turks, and Moroccans in the Netherlands; immigrants in

Finland; Blacks, Asians, and Arabs in Ireland; and multiple ethnic minority populations in the United Kingdom found that discrimination is positively associated with psychological distress. Ongoing research is also exploring these relationships in Australia, Brazil, New Zealand, and South Africa.

Measures of perceived discrimination have also been studied in relationship to multiple measures of physical health. Studies using a single-item global self-rated health measure and other self-ratings of health or checklists of chronic illnesses have also fairly consistently documented that discrimination is related to poorer health status. Two studies found that discrimination makes an incremental contribution above socioeconomic status (SES) in explaining Black-White differences in self-reported health status. Several studies have also examined the association between discrimination and blood pressure levels or hypertension. Some studies found a clear positive association between discrimination and elevated blood pressure, whereas others found that this effect varies with the coping style, sex, SES, or race. Still other studies found no association between discrimination and blood pressure.

Recent research has also paid attention to a broader range of health outcomes. Whereas perceptions of discrimination were unrelated to self-reported heart disease in some early studies, recent research documented a positive association between chronic discrimination and the onset of subclinical heart disease (intima media thickness and coronary calcification). Recent studies also found that maternal exposure to discrimination was associated with preterm deliver and low birth weight. Several studies have also examined the association between perceived racial bias and health behaviors. They have found a positive association between discrimination and cigarette use and alcohol consumption.

Understanding the Context of Discrimination and Responses to It

Some of the inconsistency in findings in studies of discrimination and health could be due to inadequate attention to characterizing the social and psychological context in which discrimination occurs as well as the specific characteristics of the discriminatory incident. First, personality characteristics could predict variations in the association between discrimination and health. Beliefs about the self, such as self-esteem, mastery, racial consciousness, and identity might affect an individual's appraisal and thus the potential threat of a discriminatory experience. Second, contextual variables such as social support could also enhance an individual's capacity to cope and respond

to discriminatory experiences. At the present time, we do not have a clear understanding of the contextual factors that can foster either vulnerability or resilience to perceived bias.

Third, specific characteristics of the discriminatory experience and its particular context can be important determinants of its impact. Key aspects of discriminatory experiences include the type or domain in which it occurs, the magnitude of the incident, its temporal characteristics (acute versus chronic), and the nature of the relationship between this stressor and other race-related and non-race-related stressors. Inadequate attention has also been given to the extent to which the effects of discrimination may vary by the social characteristics of the perpetrator. For example, some limited evidence suggests that the negative health impact of perceived discrimination on African Americans is greater when the perpetrator is also African American than when the perpetrator is White.

Fourth, it is also likely that there are complex interactions between exposure to discrimination and particular coping strategies or styles. In addition to examining traditional problem-focused and emotion-focused measures of coping from the stress literature, research on discrimination needs to attend to discrimination-related measures. Heightened vigilance is one such measure. Because racism is often deeply embedded in the structure and culture of society, it can pose an ever-present threat for socially stigmatized groups. Some individuals respond to this by engaging in psychological and behavioral anticipatory coping strategies to mitigate the perceived dangers in the environment. This can lead to heightened physiological arousal that can adversely affect health. Using denial as a coping strategy is a theoretically important but difficult concept to measure. The literature suggests that, because experiences of discrimination can pose threats to the self, some individuals respond to its occurrence by minimizing or even denying its occurrence. There is also the suggestion in the literature that denying the occurrence of bias is damaging to health.

Measurement Issues

A prerequisite for understanding the association between discrimination and health is the development of valid and reliable measures that fully characterize exposure to discrimination. The literature identifies several issues that affect the appropriate assessment of discrimination.

Perceived Discrimination Is Subjective

An important issue in the assessment of discrimination is the challenge of obtaining valid and reliable

indicators of subjective phenomena such as experiences of discrimination. It is possible that the salience of racial identity or perceived racism could lead some minority group members to perceive incidents as racist that may not be or, worse, could lead to the development of a mind-set in which they perceive experiences to be products of racism when in fact they were not. In fact, some limited evidence suggests that the use of discrimination terminology, in which race or gender is made salient in the assessment of discrimination, can induce respondent biases. This work emphasizes that questions with embedded terminology require both a description of an experience as well as an interpretation of that experience. Moreover, in the cooperative context of a research interview a respondent may make inferences about the questioner's intent and interests that could lead the respondent to try to provide information that is consistent with the questioner's perceived intent. All of this can lead to interpretive response bias that could produce higher estimates of discrimination, driven by the specific terminology used. Thus, questionnaires that ask repeated questions about "racial discrimination" or experiences "because of your race" could produce demand characteristics in which the respondent believes that it is desirable to the interviewer to report such experiences. This could lead to overreports of discrimination.

One promising approach in measuring discrimination seeks to reduce the salience of race by first asking respondents whether they have been treated "unfairly" in multiple domains of life. After respondents have endorsed an experience of unfair treatment, they are asked to attribute a reason. Potential reasons include race and ethnicity, but also allow for other factors such as gender, age, religion, weight, and sexual orientation. This approach enables respondents to report on all instances of unfair treatment, but allows the researcher to separate instances attributed to race from those linked to other reasons. Relatedly, this measurement approach allows for the evaluation of the extent that discrimination based on race is more deleterious to health than discrimination based on other social factors. Inadequate attention has been given to the relative impact of racial discrimination compared to other types of discrimination in the extant research to draw firm conclusions. However, some studies suggest that it is the generic perception of unfair treatment that is deleterious to health, irrespective of the specific attribution regarding the cause of the incident. Research is needed to identify the optimal approaches to the measurement of racial discrimination.

The available evidence suggests that concerns about the overreporting of discrimination may be

overblown. First, making race salient in the assessment of discrimination can lead to underreporting of discrimination. Respondents vary in their thresholds of what constitutes discrimination and may fail to report as discriminatory incidents that were not perceived as very serious. Second, respondents appear to interpret the concept of discrimination as intended by researchers and self-reports of discrimination are consistent with objective experiences. Third, two studies have documented that baseline mental health status (psychological distress and major depression) is unrelated to subsequent reports of discrimination. Fourth, because reporting discrimination can negatively affect self-esteem and perceptions of control, at least some stigmatized group members are likely to minimize and deny experiences of discrimination. Thus, underreporting is as important a threat to the validity of self-reports of discrimination as overreporting. Nonetheless, it is important for researchers to adjust reports of discrimination for potentially confounding psychological characteristics such as social desirability, neuroticism, and other indicators of negative affect. Such adjustment strengthens the methodological rigor of a study and increases the likelihood that observed associations between perceived discrimination and health are not distorted by underlying psychological factors. Including such controls is especially important when the measure of health status is also based on self-report.

Several strategies that have been used to improve the accuracy of the reporting of stressors should also be applied to the study of discrimination. These include the use of cues to memory (such as visual representations and reminders of personally salient events), wording the questions in ways that clearly indicate the domain of the experience being captured, and using a life-events calendar to facilitate dating the onset and resolution of experiences of discrimination.

Perceived Discrimination Is Multidimensional

Capturing the exposure to discrimination in its full multidimensional complexity and assessing the cumulative burden of such exposure over the life course is also another major challenge. Some early studies of discrimination used single-item measures. Such assessment understates the actual level of discrimination. However, many current studies assess exposure to discrimination using retrospective recall to capture exposure within a 30-day, 1-year, 3-year or lifetime time frame.

Comprehensively capturing discrimination requires its assessment in multiple areas of social life. Like other stressors, discrimination is multidimensional and should be assessed in all relevant domains. The stress literature indicates that the most commonly

measured types of stressors include life events, chronic stress, and daily hassles. Life events are major discrete stressors that are readily observable. Daily hassles are minor but often chronic irritations. Chronic stressors are ongoing problems that are typically role-related. There are analogues to all of these types of stressors in current measures of discrimination. Major acute experiences of racial bias are the most commonly assessed type of discriminatory experience. The literature on stress indicates that chronic stressors may be stronger predictors of the onset and course of illness than acute life events. Scales such as the Everyday Discrimination Scale attempt to capture persistent and recurring everyday chronic minor experiences. Future research needs to give more attention to capturing the frequency and duration of chronic discrimination in multiple social contexts, such as employment, educational, and public settings.

Other major types of stressors include traumas, nonevents, and macro-stressors. Developing analogs of these in the assessment of discrimination is a promising direction for future research. Traumas are acute stressors that are severe and overwhelming in impact, such as being kidnapped or raped. Macro-stressors are large-scale systems-related stressors such as economic recessions. Nonevents are desired and expected experiences that fail to occur. The stress literature indicates that the various types of stressors can have independent effects on health. Therefore, assessing all relevant types of stressors is a requisite to an assessment of the full impact of stress on health.

A small but growing body of research on historical trauma and its intergenerational effects on the health of American Indians illustrates the benefit of expanding our definitions of race-related stressors. Historical trauma is viewed as a cumulative and collective psychological wounding over the life span and across generations as the result of the history of genocide and assimilation that American Indians experienced at the hands of Europeans. Studying historical trauma among American Indians is not unlike existing studies of other generational group traumas, such as studies of the effects of the Jewish Holocaust on the physical and mental health, as well as the social, economic, and political contexts, of descendants of Holocaust survivors. It has been argued that historical trauma contributes to a host of issues in the American Indian population, including unresolved grief, alcoholism, depression, anxiety, high rates of suicide, homicide, problematic gambling behaviors, domestic violence, child abuse, poverty, low education levels, and various physical diseases. The literature recognizes that although the concept of historical trauma is theoretically intuitive, there are challenges

in distinguishing historical versus contemporary experiences, understanding how historical trauma is imparted across generations, and defining and measuring the levels of historical trauma. However, scales with good psychometric properties have been developed to assess historical trauma and find that as many as one-half of American Indians think regularly about these historical losses. Moreover, recent empirical studies have found support for an inverse association between historical trauma and health. Clinical interventions to address historical trauma have also been developed. A promising area of research would be to examine the generalizability of this pattern across health outcomes and American Indian cultures, as well as, seeing whether other highly visible traumatic historical events have similar effects for other groups.

Capturing Life Course Exposure

There are important measurement challenges in terms of identifying the appropriate questions that could capture the duration and frequency of discrimination over the life course. An isolated experience of discrimination, just like a random stressor, is unlikely to have long-term negative effects on health. The literature suggests that the key issue is being able to identify discriminatory experiences that are enduring and chronic. A life course perspective is critical in assessing the cumulative burden of discrimination over an individual's lifetime. Measures that do an excellent job of capturing exposure to all of the relevant types of discrimination do not currently exist. Overcoming the challenges linked to declines in the accuracy of recall with the passage of time will not be easy, but this is crucial to obtaining better measures of lifetime exposure to discrimination. Such data are necessary to begin to identify the lag times between exposure to discriminatory stressors and adverse changes in health. Life course assessment of discrimination must also be coupled with an equally comprehensive measurement of other types of stressors. The present-day literature does not provide a clear understanding of how experiences of discrimination relate to other stressors and combine, in additive and interactive ways, to affect specific health outcomes and trajectories of health status over time.

Attributional Ambiguity

Perceived discrimination is based on the perception of the individual. The subjective nature of discrimination and the ambiguity that occurs in much interpersonal interaction can lead to uncertainty regarding the attribution of specific incidents of bias or unfair treatment. It is possible that having to make sense of ambiguous social interactions can be physiologically stressful. The worry and rumination regarding the

causes of experiences of discrimination may be an added burden that can be consequential for the health of nondominant group members. It is thus possible that the degree of ambiguity attending the perception of a discriminatory experience could negatively affect health. This issue deserves careful examination in future research.

Pathways from Discrimination to Health

Researchers have generally found a weaker association between discrimination and health for measures of physical health than for measures of mental health. Physical health outcomes typically assessed are chronic conditions involving complex etiological factors and varying patterns of development and progression over long periods of time. Greater attention needs to be given to the hypothesized pathways by which discrimination might affect health and to identifying the appropriate points along that pathway at which the individual is more vulnerable to exposure to discrimination and other stressors.

The stress literature reveals that one way that stressors can affect health is by giving rise to negative emotional states, such as anxiety and depression, which in turn can directly impact biological processes or patterns of behavior that affect disease risk. Accordingly, one of the pathways by which discrimination can affect physical health outcomes may be indirectly, through psychological distress. Thus, discrimination may lead to elevated psychological symptoms, which, in turn, may lead to chronic physiological arousal. In addition, the negative emotional states created by experiences of discrimination might lead to health behaviors that may ultimately affect disease risk, such as impaired sleep patterns, decreased physical activity, increased substance use, and consumption of more food than usual. It was noted earlier that prior research indicates that discrimination is positively associated with alcohol consumption and cigarette smoking. These and other health-related behaviors may be a pathway by which perceived bias has health consequences. The stress of discrimination and the negative emotional states created by it could also lead to lower levels of adherence to medical recommendations. This latter mechanism has not yet been explored in the literature. The potential effects of discrimination and other stressors on medical compliance emphasize the need to assess the contribution of discrimination not only to the onset of disease but also to its severity and course.

Our understanding is currently limited regarding how exposure to discrimination leads to changes in particular biological responses and health behaviors. Further research is needed to identify the

physiological mediators of the effects of discrimination so that the specific biological pathways by which discrimination can adversely affect health may be studied. Such research should assess the conditions under which specific physiological systems, such as the cardiovascular, neuroendocrine, and immune systems, are affected by particular types of discrimination. We are presently unaware of the genetic and psychological factors that can lead some organ systems to be more vulnerable than others to the effects of discrimination on health.

Conclusion

Scientific research indicates that perceived discrimination is associated with poor health status, with the association being strongest for mental health. However, existing evidence does not clearly indicate the extent to which exposure to perceived discrimination leads to increased risk of disease, the conditions under which this is more or less likely to occur, or the underlying mechanisms and processes linking this stressor to health status. Advances have been made in the conceptualization and measurement of discrimination, but there is still more work to be done. The most urgent need is for the theoretical identification and the empirical verification of the plausible pathways by which experiences of bias can affect various health outcomes. At the same time, this field of research is clearly moving from infancy to childhood. The literature has now identified major gaps in this area, as well as promising conceptual, methodological, and analytic tools that are needed for the rigorous examination of the association between perceived discrimination and multiple indicators of health.

The Recovery Concept
Relevance of Recovery
Factors Influencing Recovery
Recovery from Job Stress
Conclusion

The Recovery Concept

Research differentiates between two core phenomena related to the stress process: reactivity and recovery. Reactivity refers to the ensuing physiological and psychological changes caused by a stressor and is reflected in the elevation of strain indicators compared to a baseline. Recovery refers to the processes during the poststressor period, when strain indicators return to their baseline levels. Slow recovery from the stressor can be seen as one instantiation of prolonged activity. The duration of the recovery process differs widely among the various indicators. For example, under normal conditions, blood pressure and heart rate recover within a few minutes after the termination of the stressor. However, it can take much longer until neuroendocrine parameters reach the prestressor levels. For example, a literature review based on a total of 77 studies concluded that norepinephrine recovery was complete within 1 h after the termination of the stressor, whereas adrenaline levels often remained elevated, particularly when urinary measures are used. Meta-analytic evidence suggests that salivary cortisol recovery is completed within 40–60 min after the termination of the stressor. Subjective variables such as mood may take hours to return to prestressor levels. Overall, studies show that the time needed

for complete recovery largely depends on person-specific and situation-specific factors.

In laboratory research, recovery most often is initiated by a poststressor rest period, during which the stressor is absent. The degree of recovery can be analyzed with several methods, with curve-fitting and related approaches being the most promising and reliable ones, particularly for analyzing cardiovascular recovery. In field research, it is more difficult to identify recovery periods exactly. For example, when examining recovery from job stress we might regard the weekend as the recovery period. However, this perspective assumes that during the weekend no other stressors (e.g., from the family domain) are present.

Relevance of Recovery

Quick recovery after the termination of a stressor is assumed to be an adaptive response pattern, whereas slow recovery is assumed to be maladaptive. Slow recovery implies that stress responses such as elevated blood pressure or increased levels of catecholamines and cortisol persist over longer periods of time and therefore might harm the organism. For example, McEwen argued that a prolonged allostatic response is one of the core processes that contributes to allostatic overload and subsequently might lead to illnesses such as cardiovascular diseases.

Empirical evidence that the recovery process is crucial for health comes for example from a longitudinal study on nurses. Elevated cortisol levels after work (but not during work) predicted health-care costs 5 years later. Pieper and Brosschot summarized empirical studies demonstrating that prolonged cardiovascular recovery after a stressor predicted general heart rate and blood pressure levels 3–6 years later. A recent study with a community sample points in a similar direction. Individuals who showed slow systolic blood pressure recovery from psychological tasks had elevated clinical systolic and diastolic blood pressure levels 3 years later, even after controlling for the initial clinical blood pressure levels and other variables such

as body-mass index, education, and use of tobacco products. However, before we draw any causal conclusions about slow recovery being the cause of elevated clinical blood pressure levels, we must take into account that cardiovascular risk factors such as race or lack of fitness tend to be related to slow cardiovascular recovery and might cause both slow recovery and high chronic blood pressure.

Factors Influencing Recovery

Research suggests that slow recovery is associated with personal as well as situational factors. For example, individuals with negative emotional dispositions show elevated cardiovascular parameters during poststressor periods. The findings are particularly impressive with respect to hostility. Specifically, hostile persons show elevated levels of systolic blood pressure during sleep. Similarly, in experimental settings that involve the confrontation with a stressor, high hostility is associated with slow systolic blood pressure recovery. In addition to hostility, low self-enhancement (i.e., the tendency of not experiencing highly favorable cognitions about oneself) is related to slow cardiovascular recovery during the poststressor period.

Not only cardiovascular recovery, also cortisol recovery might be hampered by personal factors. Meta-analytical findings show that clinically depressed individuals show higher cortisol levels during the poststressor period than do nondepressed individuals (but not higher baseline or reactivity levels). Moreover, people with low self-esteem show elevated cortisol recovery levels after the experience of failure. In addition, gender and race might also play a role with respect to recovery processes.

With respect to situational factors associated with slow recovery, we can differentiate between acute situational factors present in the specific setting and more chronic situational variables. Acute specific situational factors related to slow recovery refer to the type of stressor and to processes during the poststressor period. Compared with other acute stressors, emotionally involving and anger-provoking situations are associated with a greater delay in cardiovascular and cortisol recovery. It is important to note that slow recovery after the provocation of anger seems to be particularly prominent in men, as opposed to women.

Adrenaline recovery is prolonged after highly demanding situations characterized by a low degree of controllability. With respect to field situations, research suggests that, particularly after periods of high workload and high work intensity, the recovery of adrenaline is delayed.

When it comes to activities that affect recovery during the poststressor period, distraction from the preceding stressor seems to be highly important. Situations that offer distractions from the stressor support faster recovery than situations that allow individuals to ruminate about the stressful event. In addition, music – particularly classical music – helps to reduce blood pressure levels during the poststressor period.

In addition to factors associated with the situation in which the stressor occurs, chronic stressors and other chronic factors may impact recovery processes. People who are exposed to chronic stressors show delayed blood pressure and immunological recovery from acute stressors. Not only chronic stressors but particular stressors in combination with lack of resources are related to slow recovery. For example, in a study with firefighters, it was found that individuals who had experienced major life events during the past 12 months and who received only little social support in various life domains displayed particularly slow cardiovascular recovery. Results from several studies in the work context point in a similar direction. Employees in high-strain jobs (i.e., jobs associated with a high level of demands and low control at the same time) show prolonged cardiovascular and cortisol recovery. However, note that this picture is not consistent across all studies.

Prolonged recovery in people facing stressful life situations is also reflected in research using subjective measures. Individuals in stressful jobs experience a higher need for recovery and feel that it takes them longer to unwind from work. The subjective need for recovery is related to both neuroendocrine parameters and indicators of impaired well-being such as psychosomatic complaints and burnout.

To sum up, personal variables such as hostility or depression are related to slow recovery. Among the most important situational variables that are associated with prolonged recovery are situations that are anger-provoking and emotionally involving and situations characterized by high workload. In addition, chronic background stressors and lack of resources (e.g., low social support) make it more likely that recovery is delayed. With respect to factors that promote recovery, distraction from the stressful situation seems to be highly important.

Recovery from Job Stress

Compared to the vast research on stress at work, research on recovery from work demands is still rare. Often, the research just implicitly assumes that being away from the workplace (such as during vacation, weekends, or during the evening) leads to

recovery from work demands. When an individual is no longer confronted with work demands or work-related demands, recovery can occur. Thus, during leisure time individuals should avoid any work-related demands in order to recover from work demands. We review next empirical evidence on recovery from work demands focusing on recovery during vacations and weekends as well as on recovery during the evening of a workday.

Vacations and Weekends: Effects on Well-Being and Performance-Related Aspects

Vacations as a time away from work give the opportunity for people to recover from work demands and to build new resources. Empirical research on different employee groups and from different countries indicates that vacations are associated with an increase in employee health and well-being. For example, measuring levels of burnout before, during, and after vacation, a study in Israel found a decrease in self-reported burnout after vacation. Furthermore, vacations seem to have a positive impact on psychophysiological indicators such as the immune system or even mortality.

So far, there is only little research on effects of vacation on performance-related outcomes. One study examined the impact of vacations on individual perceptions of effort and task performance at work. Comparison between pre- and postvacation measures indicated no change in task performance. However, study participants reported needing much less effort to get their work done after vacation compared to before vacation. A study measuring changes in employee absenteeism rates found a decrease in absenteeism after vacation compared to prevacation. In summary, although there are the first indications that vacations have a positive effect on performance-related variables, more research seems necessary.

Research further suggests that the positive effects of a vacation subside within a short while after the employee's return to work. This means that well-being and performance-related outcomes return to their prevacation or chronic level. Such fade-out effects have been found within the first few weeks after vacation. Future research should include additional measurement occasions after vacation to better understand the fade-out of recovery effects over time and to possibly reveal factors that may impair or accelerate the fade-out process.

In addition to research on the general effects of vacation, there is some research examining specific variables in the context of a vacation that may promote recovery from work demands. For example, a study found that thinking positively about one's job, pursuing activities that include the experience

of mastery, and relaxation during vacation were associated with higher levels of individual well-being after vacation. In contrast, reflecting about one's job in a negative way and facing high levels of nonwork hassles during vacation, as well as high levels of workload directly after vacation, were detrimental for employee well-being and for performance-related variables directly after vacation. In addition, research revealed a positive relationship between people's satisfaction with the vacation and job and their satisfaction with life after vacation. However, more research is necessary to more clearly understand the processes during vacation that underlie changes in well-being and performance-related outcomes.

So far, research on recovery during the weekend is rare. However, one study found effects of specific experiences during the weekend on well-being and performance-related variables after the weekend. Specifically, reflecting positively about one's job and social activities seemed to promote recovery during the weekend, whereas nonwork hassles during the weekend seemed to be detrimental for recovery from work demands. There clearly is the need for more research on recovery from work demands during weekend to better understand the processes that enhance or hinder recovery processes and subsequent well-being and performance.

Recovery during the Evening of a Workday: Effects on Well-Being and Performance-Related Aspects

Recently, research has started examining how employees unwind from work during the evening of a workday. Research indicates positive effects of recovery during the evening on feelings of well-being at bedtime. Specifically, low-effort activities and social and physical activities seem to promote recovery and increase subsequent well-being. In contrast, household and work-related activities seem to impair recovery from work demands, as indicated by lower levels of well-being at bedtime. In addition, generally experiencing off-work activities as positive or as recovering seems to positively impact well-being at bedtime.

With regard to performance-related aspects, a study demonstrated that higher levels of individual regeneration in the morning due to recovery activities the evening before were positively associated with work engagement and proactive behaviors during the workday. Future research should examine the processes underlying those positive effects in more detail.

There is some empirical evidence that the choice of recovery activities during the evening and their effectiveness may be affected by work conditions. For example, job stressors (e.g., time pressure and low

control) seem to be associated with higher levels of job-related rumination after work, more difficulties detaching from work, and less time spent on sport activities. In addition, long work hours seem to be related to a lower capability to relax after work and again to more difficulties detaching from work and less time spent on sport activities.

Finally, the choice of recovery activities and their effectiveness may be affected by interindividual differences. For example, employees who are high in job involvement seem to detach less from work in the evening than employees low in job involvement. Research further indicates a positive relationship between the individual expectation to benefit from the recovery activities and detachment from work during the evening.

Conclusion

Research on stress recovery is a highly important topic that addresses both fundamental and applied questions. With respect to more fundamental research, theoretical models and empirical studies on recovery will add to our full understanding of how stressors affect the organism. Increasing empirical evidence suggests that not just the immediate reaction to a stressor, but processes related to stress recovery play a crucial role in the development of diseases. With respect to more applied questions, it is important to study in more detail the factors that promote quick recovery. Here, a combination of laboratory studies and studies in real-world field setting seem to be particularly promising.

Glossary

<i>Free radicals</i>	Molecules with one or more unpaired electrons that are not controlled by their immediate environment.
<i>Oxidative stress</i>	A disturbance in the prooxidant-antioxidant balance in favor of the former that enhances the potential for damage.
<i>Reactive oxygen species</i>	Higher-energy-state forms of oxygen or partially reduced forms of molecular oxygen that have increased reactivity.
<i>Redox balance</i>	The balance between oxidation and reduction states of cellular molecules. Because some molecules must be oxidized when another is reduced, the overall redox balance is inviolable. However, this balance can be altered between subcellular locations or cells.
<i>Reductive stress</i>	A disturbance in the prooxidant-antioxidant balance in favor of the latter that enhances the potential for damage; the result of a cell (or subcellular location) becoming relatively more reduced than normal.

Introduction

The ultimate goal of understanding the biochemical and molecular changes associated with stress is to find pharmacological or gene-based methods of protecting at risk tissues from injury or reversing any injury once it has occurred. The induction of stress at the cellular level can occur as the consequence of exposure to various xenobiotics, physical agents such as heat or radiation, or certain diseases. The specific

focus of the current chapter is reductive stress. This type of stress involves alterations in how and where reducing equivalents are generated and used by tissues as cofactors in normal metabolic processes, in various defense systems (particularly oxidant defenses), and in controlling various signal transduction and gene regulation pathways.

Because reducing equivalents are intimately involved in mitochondrial respiration and the generation of energy, reductive stress is most commonly generated through alterations in these pathways, including simple oxygen deprivation. This later process is often followed by reoxygenation, which can produce a sudden burst of oxidants. Thus, reductive stress and oxidative stress are inextricably linked.

Reduction–Oxidation Chemistry

The chemistry of oxidation–reduction reactions is straightforward and easily defined. Specifically, reduction is defined as the addition of one or more electrons to a molecule, whereas oxidation is defined as the removal of one or more electrons. Basic chemical principles dictate that a balance between oxidation and reduction is required in all chemical reactions. Thus, when one substance is oxidized, some other must be reduced.

At the cellular level, life can be defined as the ability to maintain gradients across membranes. Such gradients require an input of energy and may involve ions or molecules. Although at a global level the maintenance of an overall redox balance is inviolable, such a balance is a steady state and can be shifted among different classes of molecules that have different impacts on cell function or between cellular compartments. As a result, individual cells, or areas within a cell, can experience reductant (and obviously concomitant oxidant) imbalances. Significantly, these imbalances do not necessarily deviate from neutrality because, under normal conditions, the presence of substrates used by cells to generate energy means that the intracellular environment of a cell is reduced relative to that found extracellularly.

Because of the reducing nature of the intracellular environment, imbalances toward oxidation tend to be both more common and more studied. A search of the Medline database through March 2006 turned up 38 902 papers using the keyword term oxidative stress but only 43 using the term reductive stress. Despite this huge imbalance in emphasis, the reducing side of the equation is important when it comes to stress and the molecular regulation mechanisms of gene expression.

Definitions

The term oxidative stress was initially defined, by Helmut Sies in 1985, in biological systems as “a disturbance in the prooxidant-antioxidant balance in favor of the former.” This definition was later extended to include the adverse functional consequences of such stress by adding “leading to potential damage.”

The first use of the term reductive stress was by Albrecht Wendel in 1987. Interestingly, the term has never been precisely defined, perhaps because of the obvious inverse relationship to oxidative stress or perhaps because reductive stress has not been widely considered experimentally or theoretically. In general, reductive stress has been related to conditions of respiratory inhibition and refers to situations in which the status of a cell (or subcellular compartment) becomes relatively more reduced. Such situations actually end up enhancing the formation of reactive oxygen species (ROS), making the links between reductive and oxidative stress even stronger.

There is a strong tendency to imply that stress and damage are synonymous. Overcoming this tendency is difficult because damage clearly is accompanied, and usually preceded, by some sort of stress. A definition of damage may help, but there is no consensus as to what constitutes damage in a biological system. The definition of oxidative (and by analogy, reductive) stress given here indicates that stress only enhances the potential for damage, not that damage has occurred. Because the tissue changes that are routinely measured to assess reductive stress have been also observed in situations that are not necessarily detrimental to tissue or cell functions, it is obvious that stress and damage are not synonymous.

Injury, damage, toxicity, and related terms are qualitative descriptors of changes in various indices that are measured to assess cell or tissue function. Just how significant any particular change is in terms of function is rarely assessed, and thus their meaning is a value judgment made by an individual investigator. It is also important to differentiate adaptive responses from acute responses to a stress. Whether or not any observed changes are directly deleterious to function is also important, as is the time frame being considered because the persistence of some initially nondamaging adaptation can become detrimental. One useful working definition of injury is any alteration that diminishes essential functions, whether or not cell death ensues. Of course, it must be remembered that even cell death is not always undesirable, as evidenced by apoptosis under normal conditions.

Assessing Reductive Stress

A measurable shift to a more reduced steady state of some biomolecular pool is a reasonable working definition of reductive stress. The biomolecule selected for such a determination will probably differ from that used to identify the presence of oxidative stress. For example, glutathione disulfide (GSSG) is often measured as an index of oxidative stress because it only forms as the result of oxidative processes. Measuring increases in reduced glutathione (GSH) as an index of reductive stress is not, however, feasible because of cellular controls on GSH content and the large basal levels of this thiol (in contrast to GSSG). This means that small changes would need to be detected on a large background. In general, assessing the relative NAD(P)(H) pools has proven to be the most widely used indicator of reductive stress. Other indicators include an increase in the lactate/pyruvate ratio or the β -hydroxybutyrate/acetoacetate ratio.

Causes of Reductive Stress

Oxygen Deprivation

The proximate cause of reductive stress during oxygen deprivation (e.g., hypoxia or ischemia) is the loss of the terminal electron acceptor (oxygen) and the resultant accumulation of reduced cofactors (such as NADH and NADPH) along with oxidized substrates. Because this process occurs in the mitochondria, it is this organelle that first exhibits measurable changes, mainly the accumulation of the pyridine nucleotide, NADH. In the whole cell, there is also a loss of high-energy phosphates (mainly ATP). Glycolysis can modify the loss of ATP (although not enough to maintain long-term tissue viability) but at the expense of generating a further quantity of reducing equivalents. Because different tissues, as well as tumor cells versus normal cells, have differing glycolytic capacities, the extent of reductive stress induced by oxygen deprivation varies. There is no evidence to suggest that the oxidized substrates or reduced cofactors are directly toxic, but it is possible that excess reducing equivalents in the form of NADH might drive reactions in directions not normally seen, thereby affecting cell function and ultimately viability. Mechanisms of such effects could involve the generation of free radicals or the disruption of redox-regulated signal transduction pathways (Figure 1).

The ability of a tissue to maintain a normal redox balance is believed to be energy-dependent. This concept is supported by studies showing oxidants are more toxic to energy-depleted hypoxic cells than to

Figure 1 Reductive stress is a situation where the status of a cell (or subcellular compartment) becomes relatively more reduced. Causes of reductive stress can include hypoxia or ischemia and xenobiotics that affect pathways creating and/or using reducing equivalents. As the intracellular milieu becomes more reduced, there can be changes in various signaling pathways that required a defined redox state to be active. Although such effects may be detrimental, the presence of extra reducing equivalents may enhance a cell's ability to respond to an oxidative stress.

normal cells. However, although the production of energy and reducing equivalents are closely linked, they are separate biochemical events and alterations in the supply of reducing equivalents alone has the potential to induce stress.

Xenobiotics

Reductive stress in response to xenobiotics closely resembles that associated with oxygen deprivation. In fact, a widely studied model of reductive stress is termed chemical hypoxia and involves the blockade of mitochondrial respiration at several sites using cyanide and iodoacetate. Although differing from hypoxic hypoxia in some respects (e.g., chemical hypoxia appears to have more effects on NADPH than does oxygen deprivation), the overall biochemistry appears to be similar. Blocking specific mitochondrial electron transport sites with agents such as rotenone or antimycin A may also generate a reductive stress, although it is likely to have some differing effects based on the unique features of these compounds. In fact, such blockage in an aerobic environment may actually increase the generation of ROS.

Effects of Reductive Stress

The gross adverse consequence associated with prolonged oxygen deprivation is obvious – cell or tissue death. However, the biochemical and molecular changes that mediate this gross effect are much less clear. Changes consistent with reductive as well as oxidative stress have been found during hypoxia in whole animals, heart tissue, lung tissue, and chemically hypoxic hepatocytes. It also appears that disrupting cellular energy supplies, and thus reducing equivalent levels, has effects on other redox systems within the cell. For example, mitochondrial thiols are more susceptible to oxidation than are those in the rest of the cell.

Oxidative changes, or an increased susceptibility to oxidation, are consistent findings in various models of reductive stress. The oxidative changes observed in systems in which oxygen metabolism is inhibited could arise from the increased production of ROS or by modifying the cells' ability to respond to other stresses, leading to alterations in redox balance systems. The rate of mitochondrial ROS generation increases with the extent of reduction of mitochondrial

components. Although the low K_m of cytochrome oxidase for oxygen should ensure the removal of virtually all of this molecule during oxygen deprivation, it is possible that the increasingly reduced respiratory chain reacts with residual oxygen to generate ROS. It is also possible that the observed oxidative changes are a consequence of ROS generated on the resumption of respiration. Endogenous antioxidant systems may be impaired, but may continue to function during ischemia. Changes in the content of pyridine nucleotides alone appears not to lead to irreversible injury, but an altered ability to supply reducing equivalents in response to various demands may be critical.

In general, researchers have concluded that oxygen deprivation injury results not only from ATP depletion but also from reductive stress and the consequent generation of ROS by mitochondria. The site of this generation appears to be mainly at complex III, although other cellular sources of ROS appear to exist. It should be noted that not all studies support an increased mitochondrial production of ROS. For example, ROS production may not be increased following hypoxia or ischemia in the heart, brain, or isolated cardiac mitochondria.

Although clearly abnormal and likely to be detrimental in the long term, it is possible that the increased state of reduction that occurs subsequent to oxygen deprivation is actually protective against an acute oxidative stress. Similarly, under conditions of reductive stress, oxidizing agents could, in part, be beneficial because they would provide a sink for excess reducing equivalents.

The detrimental effects of reductive stress may partially be mediated by secondary effects that enhance the generation of ROS. Specifically, reductive stress can result in the intracellular release of iron which, in turn, enhances the production of ROS. Although the mechanisms are not fully understood, excessive NADH generated during a reductive stress can release ferrous iron from ferritin and can also reduce chelated ferric iron. The presence of increased amounts of free iron can, in turn, enhance the transfer of electrons to inappropriate sites, particularly in the presence of oxygen, leading to damage.

Energy and Cell Damage

Damaging events that affect cellular energy levels include mitochondrial dysfunction and the inhibition of glycolysis. Any such event will clearly affect how cells handle their supply of reducing equivalents, which is critical for cellular energy production. As cells adjust to compensate for a damaging event, reducing equivalents are shunted to functions other

than producing energy. Such shifts compound the loss of energy and must be considered potentially damaging events. Cell injury processes targeted to energy production may, therefore, represent a unique challenge for cells to increase their supply of reducing equivalents while maintaining critical redox balance to avoid further disruption of function.

The role of energy in cell injury has been studied in a variety of systems. The importance of secondary messengers in mediating such injury is well recognized. Of significance is calcium, whose intracellular levels appear to be altered in response to redox reactions as well as in the presence of energy deficiency. Changes in the levels of this cation are important for various signal transduction pathways. Thus, the regulation of signal transduction pathways by reductants is not necessarily direct, but may be mediated through secondary messengers such as calcium signaling and protein phosphorylation. Cellular pH is also important because an acidotic environment is protective against hypoxic or ischemic injury.

Pyridine Nucleotides and Cell Damage

The maintenance of reduced intracellular pyridine nucleotides appears to be a key factor in preserving cell viability because chemicals such as menadione, paraquat, and hydrogen peroxide deplete them before the loss of ATP and cytotoxicity. The key pathways maintained by NAD(P)(H) are not known, although modification of NAD(P) reduction status may lead to changes in the redox state of mitochondrial thiol groups. This, in turn, may affect cellular free calcium levels, the mitochondrial permeability transition, and trigger apoptosis.

Regulation of Gene Expression

Genes

The activation of gene expression in response to stress appears to be a universally conserved response in cells and substantial data suggest that oxidants can mediate gene activation. Whether a similar group of reductive stress-responsive genes exists is not known. It has been proposed that *grp* (glucose-regulated protein) genes are more responsive to reductive stress, whereas *hsp* (heat shock protein) genes respond better to oxidative stress.

The role of thiols in the control of cell growth and death is well accepted, although the specific pathways involved are not yet clear. Glutathione, thioredoxin reductase/thioredoxin, protein disulfide isomerase, glutaredoxin, and redox factor-1 have all been shown to affect protein thiols, thereby potentially

regulating protein folding, assembly, activity, and binding as transcription factors to specific DNA sequences. Although most work has focused on changes in terms of oxidants, it is again obvious that the reducing side of the equation could also be important. This is particularly true with thioredoxin, whose roles in regulating cell signaling are becoming increasingly appreciated.

Transcription Factors

At least 64 redox-regulated genes and transcription factors have been identified. More so than most other transcription factors, there is an extensive base of information regarding the activation of NF- κ B. This activation requires phosphorylation of the inhibitory I κ B subunit, which results in its dissociation from the inactive complex and its degradation by proteasome. A role for oxidants in NF- κ B activation is based on the observations that oxidizing conditions activate NF- κ B in several cell types, antioxidants can block this activation, and oxidant production is enhanced by various NF- κ B inducers such as tumor necrosis factor α . However, at the nuclear level, NF- κ B must be reduced in order to bind to DNA. Thus, the overall redox status of specific subcellular sites is crucial for determining the activation state of NF- κ B. Compartmentation may also be critical for the redox responses of NF- κ B-related factor 2 (Nrf-2). It has been suggested that Nrf-2 is retained in the cytosol by Keap-1 but that, when critical thiols on Keap-1 are oxidized, Nrf-2 is released and translocated to the nucleus, where Nrf-2 participates in the transcriptional activation of numerous genes. For Nrf-2 to be fully functional in transcriptional activation, a key cysteine residue must be in the thiol (reduced) form. Although phosphorylation may also be involved, this model further highlights the importance of reductive reactions in controlling signal transduction.

Activator protein 1 (AP-1) is a ubiquitous collection of protein complexes known to regulate transcription in response to environmental stimuli. It is composed of various gene products from the *fos* and *jun* proto-oncogene families. The products of these genes form homodimeric (Jun-Jun) and heterodimeric (Fos-Jun) complexes that bind to DNA, suggesting a crucial role of AP-1 in the control of cell proliferation. In addition to being stimulated by a wide range of xenobiotics or factors that promote cell proliferation, the hypothesis that cellular redox state plays an important role in the activation of AP-1 is well supported. AP-1 appears to be part of a general mechanism of regulation of gene expression following an alteration in redox balance. However, the pathways that control this expression are not clear. Antioxidants strongly activate AP-1, yet growth factor-induced AP-1 activation appears to be

ROS-dependent. Thus, although AP-1 and NF- κ B seem to respond oppositely to antioxidants, reductants and oxidants may have a role in the activation process of both factors.

GSH is clearly important for many of the reduction reactions required for normal cell functioning. In addition, recent data have demonstrated that the thioredoxin system may be the more proximal regulatory factor for several transcription factors including NF- κ B. The overall reduction status of a cell and, in particular, the relative state of both the cytosol and nucleus in terms of thiol redox balance affect the activity of transcription factors. Reductive stress is, therefore, expected to have an effect on their activities.

Conclusion

Reductive and oxidative stress are closely intertwined processes that can affect cells at various levels. Although the oxidative side of the equation has been the most studied, the reductive side has the significant potential to regulate signal transduction pathways and gene expression, as well as more obvious cellular stress responses.

Rationale for Reenactment

Common Techniques

Glossary

<i>Abreaction</i>	A process by which repressed material, particularly a painful experience or conflict, is brought back into consciousness. In the process the person not only recalls, but also relives the situation and experiences the appropriate emotional response.
<i>Catharsis</i>	The verbalization of ideas, thoughts, and expressed material that is accompanied by an emotional response and that produces a state of relief to the individual.
<i>Psychodrama</i>	A form of group therapy devised by Moreno in the 1920s drawing upon theatrical techniques to explore a patient's personality makeup, interpersonal relationships, conflicts, and emotional patterns.

Rationale for Reenactment

When exposed acutely or chronically to stressful or traumatic situations, some individuals may develop physical and emotional symptoms, which may range from bothersome to totally incapacitating. These symptoms may happen occasionally, or they can be present throughout the day and night. The aim of

having patients reenact their trauma is to prevent, diminish, or totally alleviate any potential or actual symptoms and emotional suffering. In addition to the use of psychodynamic therapy, several categories of reenactment techniques exist and are applied with respect to the clinical indication and ego strength of the individual.

Common Techniques

Debriefing

One of the most commonly utilized techniques to help individuals reenact or recall an acute or intermediate traumatic situation, debriefing can be applied in an individual or group setting. Participants are encouraged to retell their personal experiences and thereby gain an emotional release, or catharsis, that hopefully prevents or reduces the risk for more serious stress reactions. In the process, there is a sharing and education of those experiencing a common trauma that promote ventilation of feelings through the expression of emotions and the response of others.

Psychodrama

Psychodrama is a form of group therapy, but some of its techniques, such as warming up, scene setting, and therapeutic soliloquy, can be used in the individual setting as well for patients suffering from stress. Other psychodrama techniques are role playing, role reversal, therapeutic soliloquy, and mirror. The therapist or leader is an active participant. In role playing, the patient is asked to perform an impromptu dramatization of the traumatic situation. In role reversal, another individual in the group attempts to reenact what the subject may be thinking, or feeling, in the presence of the subject. In therapeutic soliloquy, the individual is encouraged to verbalize side dialogues and actions during a psychodrama scene. The mirror

technique consists of having another person reenact what the subject has done, presenting identical behaviors and expressing similar feelings to show how others experience the patient while the subject sits behind a mirror.

Hypnosis

This modality is especially useful in the reenactment of stressful or traumatic situations causing dissociative amnesia and dissociative fugue with memory loss. Hypnosis is best utilized to explore the events that precipitated the fugue or amnesia. When employing this technique, clinicians should suggest to the hypnotized patients that they may choose to forget some or even all of what was remembered or reenacted in the trance state to prevent them from being overwhelmed by the emergence of unconscious material that the patients are not yet ready to handle. The recaptured or selectively shared data from patients are then dealt with in the fully conscious state to help them cope with the underlying conflicts. It is generally advisable to employ other conscious methods before resorting to the use of hypnosis or chemical means to bring about a reenactment of a traumatic situation. While hypnosis is usually safe to use with most healthy individuals, the therapist or treater should exercise the same degree of caution in probing unconscious material in psychotherapy.

Medication-Facilitated Interviews

Clinicians may use intravenous drug-induced interviews to help patients recall or reenact traumatic situations or conflicts when symptoms may be disabling, or when great resistance is encountered in examining or recalling memories. Commonly utilized drugs include amobarbital, pentobarbital, intravenous lorazepam, and hexobarbital. A disadvantage of these interviews lies in the chemically induced amnesia that often occurs. Also, because of the risk of adverse reactions to the drugs, medication-facilitated interviews should only be performed by trained

individuals with immediate availability of life support systems and the presence of an anesthetist.

Use of Media

Young children may not have the verbal capacity to fully express their anxieties and emotional suffering when exposed to traumatic or stressful situations. Therapy may be conducted via play, painting and drawing, participation in story telling, creating illustrated storybooks, and role playing through which the trauma may be reenacted, explored and clarified, and resolved. For older children, adolescents, and adults, the creation of a documentary video or a play reenacting the trauma can prove extremely therapeutic, providing opportunities for ventilation, abreaction, clarification, reality testing, and mastery.

Scope of the Problem

Stress in Refugees

Stress-Related Disorders in Refugees

Conclusion

Glossary

<i>Depression</i>	A specific psychiatric disorder consisting of lowered mood and symptoms, such as decreased interest in most activity, loss of appetite and weight, poor sleep, fatigue, feelings of worthlessness, poor concentration, and recurrent thoughts of death.
<i>Posttraumatic stress disorder</i>	A specific psychiatric disorder following psychological trauma with symptoms of re-experiencing, such as nightmares and flashback; avoidance behavior, such as attempts to avoid thoughts and memories of the events; and hyperarousal symptoms, such as irritability, startle response, and difficulty sleeping.
<i>Refugee</i>	A person who flees to another country as a result of, or to avoid, political prosecution, war, starvation, or other disasters.
<i>Schizophrenia</i>	A severe mental disorder characterized by loss of contact with reality, hallucination, delusions, and often impairment of social and vocational functioning.

Technically, a refugee is a person who flees to another country usually to escape political prosecution, war, starvation, and other disaster. This definition does not include those displaced internally in their own country. Refugees are distinguished from migrants who voluntarily migrate to another country for economic education or personal reasons. A special group of refugees are the asylum seekers who flee to a foreign country without official recognition or on a temporary visa status and request refugee status usually because of perceived dangers if they return to their homeland. While their claims are reviewed, asylum seekers live in an ambiguous status with the threat of forced repatriation.

Scope of the Problem

At the end of 2004, the United Nations High Commission of Refugees reported 19.2 million persons of concern (including refugees, asylum seekers, stateless, and other). This was a 13% increase from 2003. Those with formal refugee status comprise 48% of the 19.2 million but many stateless persons have not been systemically identified and therefore the total persons of concern is probably much greater than 19.2 million. The areas of southern Africa and CASWANAME (Central Asia, South West Asia, North Africa and Middle East) each hosted 30% of the global refugee population. The Americas only hosted 7%. Afghanistan has been the largest country of origin of refugees despite 3.5 million Afghans in the past 3 years voluntarily repatriated home. The continual civil wars and ethnic strife in Africa and the Middle East indicates the worldwide problems of refugees and asylum seekers will continue to exist.

Stress in Refugees

Types of Stress

The stresses on refugees are diverse, multiple, and frequently catastrophic in nature. The phases of stress are often divided into preflight; flight and separation; asylum; and resettlement. Preflight stress includes poor economic conditions, food shortage, famine, political persecution, social upheaval, and violence. The results can include hunger, malnutrition, physical disability, and physical and psychological trauma. The flight and separation phase can include separation from family and society, sexual assault, violence, and collapse of social support. The result can be multiple physical and social traumas and the sense of being isolated and alone. The asylum phase often includes temporary resettlement in a refugee camp and can involve the threats of being forced to return home, inhospitable living conditions, unemployment, food shortages, and lack of health services. The results can include malnutrition, illness, and despair. Resettlement stress, often in a third country, can include unemployment, social isolation, acculturation problems, limited social ties, prejudice, language barriers, intergenerational conflicts, and minority status. The results can be severe economic hardships, social isolation, delinquency among adolescents, generational, and conflicts.

The amount of direct physical and psychological trauma varies among the refugee groups and the

amount of violence prior to and during their escape. Some, such as the first group of Vietnamese refugees, left because of fear of harm rather than direct harm or threats. Others, for example Cambodian refugees, suffered severe stress over 4 years, which involved a total collapse of their society with starvation, torture, witnessing executions, wanton deaths, forced labor for 4 years, and even violence during the escape and refugee camp experience.

There have been mass murders in the name of ethnic cleansing in Bosnia, and murder, starvation, and random lawlessness with gang violence in Somalia. Refugees fleeing severe ethnic wars, and sadistic acts of cruelty in Africa are often displayed on television. Although technically not refugees (they still stay in their own country), survivors of powerful tsunamis, hurricanes, and earthquakes experience many of the same stress as formal refugees. In general victims of acts of God have less psychiatric disturbance than those victims of man-made disasters, i.e., war.

Vulnerable Groups

At different times, different groups can be more vulnerable to stress or persecution. During armed conflict, young men are often singled out as potential enemies and severely persecuted or executed. Women are particularly vulnerable to sexual abuse (rape) when fleeing from their own country or even in settlement camps. At the country of resettlement, women and the elderly are often isolated at home and experience more difficulty in adjusting. Children acculturate faster as a result of school experience, which can greatly increase the intergenerational conflicts in the family over time.

Protective Factors

Since studies during the bombings of London in World War II, it has been shown that children that stay in the care of their mother, even in dangerous bombing situations, do better than those sent to the safe countryside away from families. An intact family or extended family that can maintain daily routines can provide some protection against the most serious psychological effects. Many studies have shown that having effective social linkages and social support provide a sense of belonging and improved identity, which protects against the stress of social adjustment.

Religious affiliations have been found to be protective in some refugee status, and strong ideological and political commitments have even reduced the effects of torture. The more massive and prolonged the psychological trauma, the less effective are any

protective mechanisms and the more consistently symptoms are found.

Asylum seekers arrive in a country on a temporary visa (or even illegally) and request refugee status. Usually, during a prolonged waiting period, their claims are reviewed, basic services are denied, and there is even the threat of forced repatriation. This group, which has been studied in several countries, has high postmigration stress and often severe pre-migration trauma. With an unclear legal status, this group is very vulnerable and may develop an increased rate of psychiatric symptoms.

Stress-Related Disorders in Refugees

Physical Disorders

The first studies of refugees occurred with Nazi concentration camp survivors who fled to another country after World War II. Their multiple symptoms were thought to be related to brain disease due to head trauma or malnutrition. Later, the symptoms were characterized as concentration camp syndrome (which is similar to posttraumatic stress disorder (PTSD)) and were found primarily to be due to the massive psychological trauma of the holocaust. Nevertheless, many refugees do suffer from head trauma, which may explain some of the complaints of memory and concentration problems.

Although long-term health effects are inconsistently found, many refugees report marked somatic distress, and 15–20% report health impairment. Among various groups of refugees (Cambodians, Vietnamese, Russians, Bosnian, and Somalis) hypertension was found in 40–50% and diabetes (type II) was found in 13–17%. Although dietary changes, refugee status, and effects of aging play a role, severe trauma contributes to high prevalence of these two diseases.

Behavioral Disorders

Refugee populations may be particularly sensitive to alcoholism, drug abuse, delinquency, or antisocial behavior. All the losses, including status and employment, may cause adult males to use alcohol and drugs as a temporary escape in both the camps and in the resettlement country. Asian refugees historically have tended to have lower rates of alcoholism, whereas Central American males tend to have high rates of substance abuse as refugees. Young people in resettlement countries have been found to engage increasingly in antisocial behavior and drug abuse. Refugee children can experience a severe disruption of family relationships and much intergenerational conflict in

their new country. A lack of effective role models, a sense of social isolation, and poor academic performance may turn adolescents to use of drugs and drug dealing in an attempt to acculturate to the host society. Such behavior by adult and juvenile males can increase family stress greatly and lead to family breakup and domestic violence.

Indeed in refugee children from Central America domestic violence (often secondary to alcoholism) is more likely to be the major trauma than war-related violence.

Psychiatric Disorders

The most persistent effects on refugees have been the consistent finding of a high rate of psychiatric disorders. Earlier reports from European refugees after World War II indicate an increased rate of schizophrenia. Later studies have shown that those refugees from the Nazi concentration camps were found to have suffered from a specific disorder characterized by fatigue, irritability, restlessness, anxiety, depression, and frequent nightmares. This concentration camp syndrome was found to be related to massive psychological trauma. The syndrome was largely forgotten; but with a large influx of refugees in the United States in the late 1970s and 1980s, it was found that many refugees suffered from PTSD. PTSD is found to be similar, if not identical, to the syndrome called concentration camp syndrome. By definition, PTSD is the result of a traumatic event in which an individual experiences or confronts death or serious injury and responds with fear, helplessness, or horror. The symptoms can cause re-experiencing such as nightmares, avoidance behavior, or a numbing experience such as efforts to avoid thoughts of the events and hyperarousal symptoms such as difficulty falling asleep, irritability, poor concentration, and startle response. In a clinic treating refugees from Southeast Asia, a 54% rate of PTSD was found among the Vietnamese refugees. The traumatic experience was related both to the Vietnam War and to the escape processes. The 92% rate of PTSD among Cambodian patients all related to the Pol Pot concentration camps. Most clinics have found PTSD to be similarly high, although the rates for Cambodians in the community (non-patients) tend to be lower. A great deal of research and clinical experience indicates that traumatized refugees have high rates of PTSD. Information exists on a number of refugees: Chilean, Salvadorian, Ethiopian Jews, Afghan, Somalis and Bosnians, as well as Tamil and Burmese asylum seekers. A recent community survey of Cambodian refugees two decades after resettlement in the United States found that 62% still suffered from PTSD. This is almost twice as high as among Cambodians living in Cambodia indicating

that refugee status and/or immigration stress contribute to ongoing symptoms. The highly televised bombing of Twin Towers on 11 September 2001 was very disturbing to refugees and many (particularly Somalis and Bosnians) had markedly increased symptoms after repeated viewing. The symptoms are often quite persistent and can recur after periods of quiescence.

Depression characterized by lowered mood, low energy, low interest, poor sleep, and poor appetite is also very high among refugees. PTSD has generally been found to be related to specific traumatic events, whereas depression relates more to postmigration stress. Depression tends to improve over time more than PTSD symptoms.

Schizophrenia, a severe mental disorder characterized by delusions and hallucinations, which is found to be high in refugees from World War II, continues to be increased in current refugees. However, the number involved is not nearly as large as those having PTSD and/or depression.

Conclusion

It is now clear that refugees suffer from much stress, sometimes of catastrophic proportions. This can result in symptoms of PTSD and depression, which are similar regardless of the culture of the refugees or the environment where the refugees resettle. As the number of refugees worldwide increases, the number of refugees impaired and suffering will continue to increase

<i>Clozapine</i>	A drug used to treat schizophrenia, called an atypical antipsychotic agent because it has a reduced tendency to cause muscle rigidity in comparison with classical drugs such as haloperidol.
<i>Raphe/parapyramidal region</i>	Neurons in the midline and ventromedial region of the medulla oblongata with direct axonal projections to the spinal cord.
<i>Thermoregulatory cutaneous vascular beds</i>	Regions of the skin (e.g., fingers in humans and tail in rats) where heat is transferred from the blood to the environment.

Introduction

During the course of evolution, natural selection has shaped behavior as well as psychological and physiological processes so that they operate in an integrated fashion, enabling the individual to successfully undertake the daily life activities necessary for survival and reproduction. During everyday life, the regional distribution of the blood flow is patterned by a combination of central command (brain-initiated) and reflex (organ-initiated) control systems, so that flow to a particular bodily organ is appropriate for the particular activity in which the individual is engaged at a particular time.

Broadly defined, an acute stress may be envisaged as the occurrence of an intrusive event (physical, psychological, or physiological) that could threaten survival of the individual or, in a broader sense, survival of the species. Such events initiate adaptive responses. W. B. Cannon appreciated that the behavioral response to stress (the flight-or-fight response) is accompanied by an acute redistribution of the cardiac output, so that blood is directed to the bodily organs involved in coping with the stressful event. This was an extremely important contribution to physiological thinking, a reminder of the concepts so graphically proposed by Darwin in his book *Expression of the emotions in man and animals*.

Cannon, however, believed the patterns of activity in sympathetic nerves supplying the blood vessels to be diffusely directed rather than regionally focused. The central command process, so Cannon thought, results in a unitary activation of all the sympathetic nerves innervating the adrenal gland and the blood vessels. At the time, this view was based on a general theoretical stance, rather than on experimentally demonstrated changes. Cannon was thinking of a highly mobile animal, actively engaged in fight or flight. In Cannon's scheme, the principal emphasis was on increases in blood flow to vascular beds in skeletal muscle. Measurement of regional blood flow or sympathetic nerve activity in a conscious behaving animal is still technically difficult, so that there is still much to be learnt. In a cat confronted with a second aggressive cat, blood flow to skeletal muscle beds appears to depend on how much the animal actually moves and on whether particular muscle groups are involved in the movement. There is no general increase in blood flow to all skeletal muscles.

Cannon was correct in his view that the response to stressful events includes diversion of blood away from the skin. The short-term (over minutes) nutrient requirements of the skin are not crucial, so that the supplying blood can be diverted elsewhere without deleterious effects to the skin itself. The skin is vulnerable to injury precisely because, as the border between the individual and the external environment, it bears the initial brunt of any actual physical attack upon the individual. If blood is diverted from the skin, the danger of major injury-induced hemorrhage is reduced. This article, drawing on experiments conducted in experimental animals (rabbits and rats), outlines some of the environmental stresses which, via the central command process, activate

cutaneous sympathetic neural outflow so that blood flow to the skin is suddenly reduced.

Exposure to Cold Causes a Sudden Decrease in Cutaneous Blood Flow

The volume of blood flowing through thermoregulatory (heat-exchanging) cutaneous blood vessels (ear pinna in rabbits, tail in rats, fingers and toes in humans) is rapidly reduced when the individual is suddenly exposed to cold (a physical stress), so that heat loss from the body is reduced. The brain, via the various sensory inputs, detects the cold environment and particular brain centers activate the sympathetic nerves innervating the blood vessels, thereby constricting the vessels and reducing the amount of blood that enters the heat-exchanging areas of the body. Since the final control neurons within the central nervous system (the sympathetic preganglionic neurons) are located in the thoracic and upper lumbar segments of the spinal cord, there must be neural connections linking forebrain, midbrain and hindbrain with these spinal neurons. The descending pathways are briefly summarized later in this article.

When the Individual is Frightened, Cutaneous Blood Flow Falls

When the individual detects potentially dangerous events in the external environment (physical or

psychological) special alerting rhythms occur in the hippocampal electroencephalograph followed, a few seconds later by a sympathetically mediated fall in cutaneous blood flow (**Figure 1a**), with a return to baseline levels after a minute or so if the danger is transient. In conscious rabbits (especially bred for use in laboratory experiments and thus familiar with humans) apparently minor stimuli (e.g., the laboratory telephone ringing or an unexpected touch of the fur) often cause cutaneous blood flow to fall suddenly to near zero levels, without change in blood flow to the kidneys, with a small decrease in blood flow to the intestines and abdominal viscera, and with no change in blood flow to vascular beds in skeletal muscle (**Figure 1b**). With relatively minor alerting stimuli there is little or no change in cardiac output. There may be no obvious behavioral change. If the animal is more strongly alerted, either because the stimulus is more threatening or because the animal is already anxious, the cutaneous vasoconstriction is more prolonged. Heat loss via the cutaneous circulation is thereby interrupted for a longer period. Body temperature may increase, a situation referred to as stress-induced hyperthermia.

One way of introducing a more threatening stimulus is to utilize the conditioned fear response. Rats subjected to an electric shock exhibit behavioral change (freezing) and cardiovascular changes. If the electrical shock is delivered soon after the rat has been moved to an unfamiliar cage, similar behavioral

Figure 1 a, Ear pinna arterial blood flow (top panel) and hippocampal electroencephalograph (bottom panel) in a conscious rabbit, recorded before and after onset of a sudden sound. After the sound onset, the electroencephalograph develops a slow (6–7 Hz) regular rhythm indicating that the sound is significant for the rabbit. Approximately 1 s after the sound, ear pinna blood flow falls rapidly to near zero levels. b, Blood flow recorded simultaneously from arteries supplying the ear pinna, intestine, kidney, and skeletal muscle in the hind limb. Ear pinna blood flow falls to near zero levels when the animal detects potentially dangerous environmental stimuli (see Yu and Blessing, 1997: R208).

Figure 2 Infrared digital images of one fear-conditioned a, and one sham-conditioned b, rat obtained during re-exposure to the experimental box. Brighter regions indicate increased temperature (i.e., higher blood flow). Note (white arrows) the fall in tail and paw temperature in the fear-conditioned, but not in the sham-conditioned rat during re-exposure to the experimental box (see Vianna and Carrive, 2005: 2505).

and cardiovascular changes occur when the rat is subsequently reintroduced to the same cage, i.e., the rat displays a conditioned fear response. Cutaneous vasoconstriction is a prominent component of the cardiovascular response (Figure 2).

Psychotropic Drugs Alter Cutaneous Blood Flow

There is an intricate interrelationship between neurotransmitters controlling emotional/psychological functioning and neurotransmitters involved in CNS neural pathways regulating cutaneous blood flow. Serotonin (5-hydroxytryptamine, 5-HT) and dopamine are important in both systems. Lysergic acid diethylamide (LSD) and related agents cause hallucinations by an agonist action at subclasses of serotonin receptors (5-HT_{2A} receptors). Ecstasy (methylenedioxymetamphetamine, MDMA) causes release of serotonin in the brain, with subsequent activation of 5-HT_{2A} receptors. These drugs also markedly activate the thermoregulatory sympathetic outflow to the cutaneous vascular bed, causing vasoconstriction and reducing heat loss from the body. Clozapine, a very valuable antipsychotic drug used in the treatment of schizophrenia and schizoaffective disorders to reduce mental stress, reverses the effects of MDMA and LSD-like agents on emotional function. Clozapine also reverses MDMA-induced activation of the cutaneous sympathetic outflow. In drug-free animals, clozapine inhibits resting cutaneous sympathetic outflow, so that cutaneous blood flow increases (Figure 3a), as well as reducing the increase in cutaneous sympathetic discharge normally initiated when the individual detects a frightening stimulus (Figure 3b).

Cutaneous Blood Flow Decreases During the Febrile Response to an Infectious Agent

Infectious agents such as viruses or bacteria cause body temperature to increase (the febrile response). Underlying physiological mechanisms include activation of the cutaneous sympathetic outflow, with constriction of the cutaneous vessels so that body temperature increases partially because heat is no longer transferred from the body to the environment.

Neuronal Pathways in Brain and Spinal Cord Co-ordinating Sympathetic Outflow to the Cutaneous Vascular Bed

Stressful environmental stimuli are detected by the different senses (vision, hearing, touch, temperature, and pain sensitivity, etc.). These afferent stimuli are processed in forebrain centers, including the amygdala and the dorsomedial nucleus of the hypothalamus. Efferent neuronal signals reach the sympathetic preganglionic neurons in the spinal cord by way of a major integrative center in the lower brainstem, in the raphe/parapyramidal region of the rostral medulla oblongata. Neurons in the raphe have direct axonal projections to the sympathetic preganglionic neurons in the spinal cord (Figure 4).

Conclusion

As the individual prepares to cope with the different forms of environmental stress, blood flow to the cutaneous vascular bed is reduced via activation of the relevant sympathetic nerves, a response initiated in the brain and co-ordinated by spinally projecting

Figure 3 Blood flow to the tail of the conscious freely moving rat measured with a timeframe of minutes (a) and seconds (b). In (a) either vehicle control solution (top panel) or clozapine solution (bottom panel) was administered. Before the injection both traces show frequent sudden falls to near zero levels in response to perception of alarming events by the animal. Tail blood flow falls during the injection procedure in both panels (the rat is alarmed by the procedure). After clozapine, resting blood flow increases and the sudden falls in flow are no longer observed. In (b) the upper panel was obtained from a control, vehicle-treated rat and the lower panel was from a rat treated with clozapine 30 min before. A sudden tap to the animal's cage elicits a rapid fall in tail blood flow, to near zero levels, in the vehicle-treated animal but not in the clozapine-treated animal (see Blessing, 2005: 518).

Figure 4 Summary diagram illustrating neural pathways linking brain and sympathetic preganglionic neurons in the spinal cord. The raphe/parapyramidal region of the rostral medulla oblongata is an important relay station in the descending brain pathway mediating stress-induced cutaneous vasoconstriction.

neurons present in the raphe/parapyramidal region of the medulla oblongata. Some drugs used to treat mental illness also interact with brain neurotransmitter systems (serotonin and dopamine) regulating the thermoregulatory cutaneous blood flow to reduce stress-induced sympathetic activation, thereby increasing resting cutaneous blood flow and preventing stress-induced falls in blood flow. Measurement of cutaneous blood flow provides a new biological index of stress.

Progressive Relaxation

Self-Hypnosis

Autogenic Training

Meditation

Biofeedback-Assisted Relaxation

Conclusion

Glossary

*Behavior
therapy*

A system of psychotherapy that views mental disorders as products of maladaptive learning that are best treated by techniques derived from classical and instrumental conditioning principles.

*Systematic
desensitization*

A technique used in behavior therapy to eliminate specific fears by requiring the patient to imagine different situations involving the feared stimulus while remaining relaxed. To avoid overwhelming the patient, the imagined situations are often mastered successively in an anxiety hierarchy, from least to most fear-provoking.

Progressive Relaxation

For centuries, the prescription rest and relaxation has been a popular treatment for a wide range of maladies. The apparent curative properties of rest were being endorsed by physicians and healers long before

a scientific basis for the association between stress and disease had been established. A seminal contribution to understanding the pathophysiology of stress was the 1929 publication of Edmund Jacobson's *Progressive Relaxation*, an empirically based treatise on the role of neuromuscular tension in various somatic, neurological, and psychiatric disorders. In this work, Jacobson noted that many instances of physical and mental disease include among their symptoms the failure to relax – an ability that is often regained following recovery. Using electrophysiological measures, Jacobson confirmed the presence of neuromuscular tension in various disorders and was able to document the power of relaxation to dissipate stress-related symptoms. He also reported that mental operations, such as imagination, emotion, and recollection, were expressed in muscle contractions, a finding that proved to be an important milestone in the development of the field of psychosomatic medicine. Thus, for the first time, there was compelling scientific evidence to support the widespread belief among medical practitioners that stress and anxiety contributed to disease states and that relaxation-based therapies provided effective treatment options for many patients.

The procedures involved in progressive relaxation (PR) developed directly from Jacobson's scientific studies of muscular tension. A fundamental tenet of this approach is that tension and deep muscle relaxation are physiological opposites that cannot coexist. Thus, to the extent that neuromuscular tension underlies a particular disorder, relaxation should be an effective remedy. Moreover, PR allows patients to become actively involved in their own treatment, a feature that Jacobson regarded as an important psychological benefit of the procedure. The broader objective, however, was to teach patients to incorporate relaxation skills into their lifestyles so that they could become better able to respond appropriately

to future stressors by controlling their tendency to become tense.

Technique

A preliminary condition of training is the use of responses that allow the patient to recognize muscle contraction (i.e., tension) wherever it is present. The procedure requires the patient to alternately tense (i.e., contract) and relax (i.e., extend) each of the major muscle groups of the body. The goal of this exercise is to help the patient to discriminate degrees of muscular tension, which can be controlled as warranted or, in extreme cases, supplanted with deep relaxation.

PR attempts to cultivate whole-body relaxation. Patients are encouraged to assume a comfortable position and relax. Then they are instructed to clench the left or right fist as tightly as possible and to notice the tension as it creeps up from the fist to the hand to the forearm. This is followed by instructions to relax the fist and to pay particular attention to the difference they feel between the tensed and relaxed states. The therapist's instructions merely guide the patient's attention to actual experiences that accompany variations in muscle tension; there is no reliance on suggestive techniques, such as hypnosis. The procedure is repeated using the opposite fist, then the upper arms, the facial muscles, the chest, the stomach, and the lower back; it culminates in the muscles of the lower extremities. Each time the patient is encouraged to become aware of the difference in sensation between tension and relaxation and to allow relaxation to come to predominate.

As originally outlined by Jacobson, the procedure involved upward of 100 training sessions, many focusing on single muscle groups. Pragmatic concerns soon prevailed and abbreviated versions were developed, beginning with the efforts of psychiatrist Joseph Wolpe, who adopted relaxation as a means to countercondition anxiety responses elicited in the context of his behavior therapeutic method of systematic desensitization. Contemporary approaches to PR attempt to promote profound whole-body relaxation in a single session. They routinely involve the alternation between tensing and relaxing groups of muscles, but the procedures take place in a matter of minutes rather than days and they frequently include hypnotic-like suggestions to facilitate relaxation.

Clinical Effectiveness

PR has been applied clinically to various medical disorders in which indicators of stress, such as sustained autonomic arousal or chronic muscle tension, are present. Both controlled and uncontrolled studies

support its effectiveness in the treatment of anxiety disorders, depressive symptoms, anticipatory nausea associated with chemotherapy, tinnitus, insomnia, low back pain, hypertension, and tension headache. The evaluation of the specific contribution of PR in treating these conditions is often complicated by the inclusion of other potentially therapeutic components in the treatment protocols. At the same time, the case for some disorders (e.g., hypertension) generally is inconclusive, owing to the fact that, on an individual basis, stress may not be a primary etiological factor. As Herbert Benson and his colleagues have noted, relaxation can lower an individual's blood pressure, but the magnitude of the effect depends on the extent to which stress plays a role in the first place. A number of studies reported in the literature on the clinical effectiveness of relaxation techniques have failed to make this important initial determination.

Finally, classical PR may not be appropriate for certain disorders, due to its potential to exacerbate symptoms. This has been reported, for example, among individuals suffering from tension headache or myofascial pain disorders, as well as with the elderly, in whom the practice of alternately tensing and relaxing relevant muscle groups actually increased pain and anxiety. Fortunately, when such complications arise, PR can be modified to omit the muscle contraction component of the exercises, which Jacobson recommended only as a means to sensitize patients to the presence of tension in their bodies. In some studies, imaginal relaxation, in which participants are not required to enact muscle tension-release exercises but merely to imagine performing them, was associated with reductions in stress symptomatology. In addition, recent efforts to customize relaxation therapy to the functional abilities of individuals with spinal cord injuries, as determined by the level or site of injury, have produced positive outcomes in several studies.

Self-Hypnosis

The use of hypnosis in stress-related conditions is another technique that seeks to engender deep relaxation, typically with the use of direct suggestions that the subject experience calm, sleepiness, and contentment (see **Hypnosis**). A preponderance of data shows that virtually all hypnotic phenomena that can be experienced in a dyadic relationship with a therapist can also be induced by the patient using self-hypnosis. This is because heterohypnosis is fundamentally self-hypnosis, and vice versa. That is, the experience of hypnosis requires an appropriately hypnotizable individual who is motivated to accomplish the goals targeted by select therapeutic suggestions administered

in a distinctively hypnotic context. By the same token, self-hypnosis can be conceptualized as an extension of heterohypnosis in which the patient carries out a procedure taught in a therapeutic relationship and is able to reinstate feelings that were originally established in heterohypnosis by imagining the words of the therapist during the self-hypnotic exercise.

Self-hypnosis is best learned with the help of an experienced hypnotherapist who outlines the clinical objectives, dispels any misunderstanding about the procedure and its outcomes, teaches techniques to induce the condition of hypnosis, and works with the patient to establish appropriate suggestions and metaphors to facilitate therapy. Routinely, skill in self-hypnosis develops as the patient practices the techniques outside the therapist's office. To encourage regular practice and to optimize the therapeutic value of self-hypnosis, however, it is helpful for the patient to maintain his or her relationship with the therapist. We have found, for example, that in the context of stress and pain management, periodic therapy sessions, or even occasional telephone contact with the therapist, can sustain the patient's motivation to practice self-hypnosis and may even compensate for deficiencies in hypnotic ability that might otherwise produce discouraging outcomes. Attention to motivational issues is, therefore, an important aspect of preparing patients for positive experiences with self-hypnosis.

In addition to the capacity of self-hypnosis to promote deep relaxation, many individuals who practice the technique as a complement to an ongoing therapeutic relationship are also able to favorably modify their perceptions regarding the importance of the stressor, as well as their emotional reactions to it. Accordingly, for patients with sufficient hypnotic ability, self-hypnosis might well be the treatment of choice for conditions (e.g., chronic pain) that fail to respond adequately to relaxation-oriented therapies alone.

Autogenic Training

Closely related to self-hypnosis is the formalized system of auto-suggestive therapy known as autogenic training (AT). It was developed by Johannes Schultz as a form of psychophysiological therapy in which patients can be taught a series of exercises to induce in themselves a profound state of physical and mental relaxation similar to deep hypnosis. The method grew out of Schultz's own clinical work with hypnosis, during which he noted that hypnotized patients commonly reported the sensation of heaviness in their limbs, accompanied by feelings of warmth. These observations were taken and interlaced with his belief

that hypnotic suggestions were successful to the extent that the patient allowed them to happen. Specifically, in Schultz's analysis, hypnotized patients adopted a type of passive concentration, permitting the suggested changes to occur without trying to directly influence their occurrence. Hence, the blueprint for AT evolved. The purpose was (1) to achieve the psychophysiological effects typical of hypnosis without the need to formally induce the condition of hypnosis and (2) to train the patient to self-administer the relevant suggestions, thereby conveying a substantial element of responsibility for treatment from the therapist to the patient.

Technique

AT can be carried out on an individual or group basis, although individual training can more readily adjust to idiosyncratic differences in rate of skill acquisition or other needs. Environmental considerations include a slightly darkened room free of distractions, with a comfortable temperature and a chair, couch, or mattress. The verbal formulas developed by Schultz and used clinically for nearly three-quarters of a century fall into three categories of autogenic exercise: standard, meditative, and special. For illustrative purposes, we outline here only the standard autogenic exercises, whose mastery is a prerequisite for advancement to meditative (involving imagery) and special (designed to treat specific organic or mental disorders) exercises. Moreover, the standard exercises are the most widely used for stress management.

- **Heaviness.** Training in heaviness usually begins with the dominant arm, with the expectation that, as the exercise proceeds, heaviness will begin to generalize to other extremities. The trainee passively concentrates as the therapist repeats calmly, several times, "I am at peace. . . . My right arm (if that is the dominant arm, otherwise, left arm) is heavy. . . . My right arm is heavy. . . . My right arm is heavy. . . . My right arm is heavy." As the right arm becomes heavier, the trainee begins to notice a sense of heaviness in the left arm as well. This is reinforced as the therapist slowly repeats, "My left arm is heavy," a number of times, followed by "Both of my arms are heavy." The exercise is then extended to induce the spreading heaviness in each of the legs, concluding with the formula "My arms and legs are heavy."
- **Warmth.** The second standard exercise is intended to induce the experience of warmth in the arms and legs by increasing blood flow in the extremities. Once heaviness has been achieved, the second formula is combined with the first: "I am at peace. . . . My arms and legs are heavy. . . . I am at peace. . . . My arms and legs are heavy. . . . My right arm is

warm. . . My right arm is warm. . . My right arm is warm.” The procedure continues with repetition of the appropriate verbal formulas and passive concentration as warmth develops in the other arm and in each of the legs, culminating with repetition of the phrase “My arms and legs are warm.”

- **Cardiac regulation.** The third standard exercise focuses on the trainees’ awareness of their heartbeat. Many trainees do not readily perceive their heartbeats unless they are hyperaroused. Such individuals may require postural alterations to sensitize cardiac awareness, such as practicing autogenic exercises with the right hand placed over their heart. The relevant verbal formula that is the focus of passive concentration is “Heartbeat calm and regular.” The objective is not to slow the heart rate but to bring it into a consistent rhythm that supports the already established feelings of heaviness and warmth.
- **Respiration.** The fourth exercise is intended to teach the self-regulation of respiratory functions. Like the cardiac regulatory exercise that precedes it, the trainees’ respiration rates should have been substantially decreased during the heaviness and warmth exercises. However, unlike heartbeat activity, the rate of breathing is relatively easy to modify voluntarily, an inclination that must be resisted if passive concentration is to be maintained. Accordingly, the fourth formula is phrased “It breathes me” to emphasize the importance of passive focus.
- **Abdominal warmth.** The fifth standard exercise attempts to induce a generalized feeling of warmth deep in the region of the solar plexus. Many trainees require an anatomy lesson to localize this target of passive concentration (i.e., halfway between the lower segment of the sternum and the navel) before the therapeutic phrase “My solar plexus is warm” can be employed effectively. The exercise is contraindicated for people with medical conditions involving the viscera of the peritoneal cavity (e.g., diabetes, gastric tumors, and ulcers).
- **Coolness of the forehead.** The final standard autogenic exercise stems from the common observation that a cool cloth applied to the forehead reduces tension – an effect that can also be achieved by a redistribution of the blood flow away from the head (i.e., localized vasoconstriction) and toward the extremities (i.e., peripheral vasodilatation as accomplished in exercise 2). The relevant supplemental autogenic formula to be repeated at this stage of training is simply “My forehead is cool.”

Training is considered complete when the trainee is skilled at the self-administration of the autogenic

program. Each of the standard exercises works toward reinforcing the others to inhibit indicators of sympathetic nervous system activation, thereby promoting a generalized state of physiological and mental relaxation.

Clinical Effectiveness

AT is widely used in conjunction with biofeedback techniques to promote stress reduction, although many clinicians employ autogenic therapy as a solitary method to achieve self-regulation of the autonomic nervous system. Attempts to assess the specific effectiveness of AT by reviewing the relevant scientific and clinical literatures are, however, impeded by several factors (e.g., small nonrandom samples, poor controls, and wide variation in training protocols and extent of training). Quantitative reviews that ignore the idiosyncratic aspects of individual studies and focus, instead, on the magnitude of the treatment effects across studies, compared to no treatment or to other nonpharmacological techniques (e.g., biofeedback, meditation, progressive relaxation, or self-hypnosis) tend to conclude that AT is as efficacious, on the whole, as other biobehavioral interventions for most psychosomatic disorders. There is, however, some evidence that AT may specifically promote decreases in heart rate that are independent of the general lowered respiratory frequencies associated with other relaxation procedures such as Jacobson’s PR technique. Stress-related conditions that are claimed to respond positively to AT include respiratory problems (e.g., bronchial asthma) and circulatory disorders (hypertension, Raynaud’s disease, tachycardia, and cardiac arrhythmia), insomnia, and anxiety.

Meditation

Meditation refers to a collection of practices, generally of Asian origin, that induce a change from the ordinary in a person’s mental focus, with the result that metabolic activity is slowed and the practitioner often feels relaxed and refreshed. Two general forms have been identified, concentrative and nonconcentrative methods.

In the concentrative approach, typified by Transcendental Meditation, the individual is seated in a quiet environment and directs his or her focus on a single repetitive stimulus, such as a word or sound recited mentally as the person takes in or exhales breaths of air. The objective is to remain single-minded. If distracting thoughts intrude, the meditator is directed to simply dismiss them and to bring his or her attention back to the focal stimulus. The technique, along with its religious and philosophical trappings,

was popularized in the western hemisphere in the late 1960s by the Maharishi Mahesh Yogi, whose disciples included many celebrities of the period.

A prominent form of nonconcentrative meditation in use medically is mindfulness meditation, which is derived from Buddhist tradition. The technique does not necessarily lead to a profoundly relaxed state, as is typical of concentrative forms of meditation. Rather, the primary goal is to obtain insight into the self by learning to catalog moment-to-moment changes in experience.

Mindfulness meditation begins with a single object of focus (e.g., breathing) to establish calmness, but the mental focus is gradually expanded to include any ambient stimuli, thoughts, feelings, and physical sensations that enter awareness. Unlike concentrative meditation, practitioners of mindfulness do not regard these experiences as distractions to be ignored but instead dispassionately focus on each until their attention wanders, whereupon they simply note where their thoughts have taken them before redirecting attention back to their in-the-moment experiences. Various formal and informal exercises have been developed to facilitate the adoption of mindfulness as a lifestyle approach to foster an appreciation for the importance of living in the present moment.

Clinical Effectiveness

A number of scientific investigations of Transcendental Meditation were undertaken in the early 1970s by Robert Wallace and Herbert Benson, which documented the ability of meditation to induce deep relaxation and to oppose sympathetic arousal. Among the physiological changes produced during meditation were substantial decreases in the rate and volume of respiration, with correspondingly reduced levels of oxygen consumption and carbon dioxide production. In addition, a slowing of the heart rate, accompanied by increases in skin resistance and decreases in blood lactate levels signified an overall reduction in anxiety or arousal. Furthermore, studies using electroencephalograms (EEGs) confirmed the presence of a low arousal state – a pattern featuring a predominance of alpha activity, with occasional brief transitions toward theta and deep-sleep-like delta frequencies. What was not found in these early studies was evidence that meditation significantly affected blood pressure, which Benson and his colleagues soon realized was due to the fact that their sample of experienced meditators had quite low blood pressure to begin with. Subsequent research determined that meditation was effective in reducing blood pressure in individuals with stress-related hypertension. Recent

studies have also found that meditation is associated with improvements in respiratory and cardiovascular functioning, sleep disturbance, and depression, as well as in the treatment of addictive disorders.

As mentioned previously, nonconcentrative forms of meditation, such as mindfulness, do not uniformly induce relaxation. In fact, although relaxation states often occur when practicing the technique, because the intended goal is greater self-awareness no particular physiological outcome should be anticipated. Nevertheless, mindfulness meditation appears to be notably useful for the management of chronic pain, in which learning to identify the everyday pain sensations apart from their emotional and evaluative components helps to lessen the degree of suffering that is otherwise endured. Preliminary evidence suggests that training in mindfulness meditation may also be of benefit in women with breast cancer by reducing stress and anxiety and improving their outlook for recovery.

Biofeedback-Assisted Relaxation

Many of the bodily processes affected by relaxation techniques are normally unavailable to conscious awareness; hence, they elude any casual attempts at voluntary control. Biofeedback rectifies this situation through the use of sensors and instrumentation capable of detecting, amplifying, and displaying the relevant biological signals. Armed with information regarding the moment-to-moment status of their blood pressure, heart rate, muscle tension, or electrical activity of the brain, patients are in a position to observe any correlations between thoughts and behavior and corresponding changes in these physiological modalities. Once such relationships are discovered, it becomes possible to achieve self-regulation of these systems with the help of biofeedback. In many cases, this self-regulation can be maintained outside the therapist's office (i.e., without reliance on instrumentation) by carrying out the cognitive or motor strategies that were previously demonstrated to affect relevant aspects of the person's physiology.

Biofeedback is used in the treatment of many disorders, some with central nervous system involvement (e.g., cognitive and attentional problems, and depression), others involving the circulatory system (e.g., cardiac arrhythmia, hypertension, and orthostatic hypotension), and others involving localized neuromuscular dysfunction (e.g., urinary or fecal incontinence and tension headache). As an aid to relaxation, however, two modalities are generally preferred: electromyographic (EMG) feedback and temperature feedback.

Electromyographic Biofeedback

EMG biofeedback is employed to monitor and display muscle tension. Although almost any muscle that can be monitored with skin surface electrodes is a viable target for EMG biofeedback, three muscle groups tend to be favored: the frontalis muscle (forehead), the masseter (jaws), and the trapezius (shoulders). The reason these muscles receive special attention is that they are particularly prone to contract during stressful situations. The goal of EMG training is to use the biofeedback information to learn particular cognitive or behavioral strategies that reliably induce relaxation in the targeted muscle site. EMG biofeedback is designed to accomplish the same objectives as Jacobson's progressive relaxation technique while permitting the patient to observe his or her progress.

Temperature Biofeedback

Thermal biofeedback is used to relay information about skin temperature to the patient. To accomplish relaxation, the patient is trained to increase the skin temperature of the hands and/or feet. The instrumentation can be quite simple (e.g., an outdoor thermometer taped to a finger or toe is usually adequate), making it convenient for patients to practice the technique at home. The physiological mechanism that supports the intended alterations in skin temperature is an increase in blood flow in the extremities, which opposes the usual sympathetic response to stress, involving peripheral vasoconstriction.

Clinical Effectiveness

Biofeedback-assisted relaxation is the most commonly employed application of biofeedback techniques. EMG biofeedback procedures have been found to be effective in the treatment of anxiety, insomnia, and various psychosomatic disorders, such as colitis, hypertension, gastric ulcers, and tension headaches. Thermal training has been particularly helpful in the treatment of migraine headache and Raynaud's disease (a vascular disorder involving the sensation of extreme cold in the hands and feet). It is frequently

combined with autogenic phrases, imagery, and breathing exercises.

Conclusion

Whether provoked by palpable adverse life events, microscopic pathogenic agents, or simply our own misperceptions and anxious thoughts, stress is an inescapable part of human experience that demands biological and behavioral adjustments. Unfortunately, when exposed to persistent stress, constitutionally vulnerable individuals or people with inadequate coping resources may suffer harmful health and psychological consequences. The development of relaxation and stress-reduction skills provides an often pleasurable and cost-effective approach to moderating the experience of stress before it takes a serious toll. An important caveat, however, is that each of these techniques has the potential to modify physiological and psychological processes in beneficial and sometimes harmful ways. It is, therefore, strongly advised that individuals motivated to develop relaxation skills consult with a qualified physician, psychologist, or dentist who can recommend an appropriate program that is, at the same time, suited to the person's lifestyle. The most significant benefits of relaxation techniques usually accrue when practice becomes part of a daily routine.

Religion as a Concept

Religion as a Cure for Stress

Religion as a Cause of Stress

Religion as a Correlate of Stress

Glossary

Apocalyptic religion

A religion based on writings prophesying a cataclysmic time when evil forces are destroyed; includes millenarian religions that focus on the end of 1000-year period described in the Book of Revelation.

Cult

A pejorative term used to describe a new religious movement, especially one that is secretive, is socially isolated, is faddish, has unfamiliar rules and rituals, and uses coercive or manipulative or deceptive techniques used to win or keep new converts.

Prophetic religion

A religion that maintains that truth is revealed by prophecy; sometimes referred to as religions of revelation. Prophetic religions include Western monotheistic religions such as Judaism, Christianity, and Islam, as well as Zoroastrianism and Bahai.

Religion

A system of beliefs centered around the concept of a supernatural being or force.

Transcendent religion

A religion that teaches techniques for transcending or transforming the reality of the senses or that denies the existence or importance of mundane reality. Transcendent religions include many Eastern religions and some Western New Age beliefs.

Religion can be both a cause of stress and a cure for stress. Some go so far as to say that it is religion's ability to relieve the very stress that it induces that is partly responsible for its tenacious hold on its truest or newest believers. It has also been noted that religious sentiment and sectarianism rises during times of increased personal or societal stress. Because change and uncertainty are potent causes of stress, on a psychological, sociological, and physiological level, it is

not surprising that some of history's most unusual religious movements have sprung up during the times of rapid social change and uncertainty. Individuals undergoing personal stress and lifestyle shifts are statistically more likely to get involved with unusual or innovative religious movements. Thus, adolescents who have recently left home, the newly divorced or bereaved or relocated, and prison inmates are especially susceptible to the appeal of new religions or radical religions. But charismatic religious groups or cults are not the only religious groups that gain momentum during times of stress; even the ranks of more garden-variety religions grow when the stresses of poverty, old age, war, illness, isolation, or impending death increase.

Religion as a Concept

Religion is anything but a single, all-embracing phenomenon. There are over 100,000 registered religions in the United States alone. The number of registered religions is increasing, not decreasing, and has been on the rise in the United States since the 1960s. The number of people who accept a personal spirituality, rather than a recognized religion, is rising even faster, to the point that spirituality is now a more politically correct and more all-embracing term that bypasses the conservative connotations of the word religion.

Even the meaning of the word religion is a source of contention. For the sake of simplicity, we define religion here as a system of beliefs centered around a supernatural being, power, or force. But, for the sake of accuracy, we must add that many well-respected definitions of religion that include systems of belief do not include a belief in the supernatural and that some well-known religions, such as Confucianism, are not concerned with a supernatural entity.

Given the large number of recognized religions in existence, it stands to reason that religions can differ dramatically from one another. Furthermore, some organized religions include far-flung sects and subsects that bear little superficial resemblance to the parent religion, and some (but certainly not all) religions host a wide variety of views on different issues. It may be tempting to think that religious beliefs, rites, customs, and concerns can be plotted out on a spreadsheet, so that different religions can be directly compared to one another. However, this straightforward approach of scientists leads to an inaccurate appreciation of the vagaries of religion and overlooks the fact that one religion stresses rites of worship,

another concerns itself with right thinking, a third revolves around prayer or penitence, a fourth focuses on gender differences and reproduction issues, a fifth emphasizes the afterlife, and so forth. It is unlikely that each religion has something to say about every aspect of life (or death), even though each religion represents itself as the ultimate authority on human life.

Religion as a Cure for Stress

Both its fiercest critics and its most fervent advocates agree that religion (or at least some religions) can dampen psychological stress. Freud himself, that arch-enemy of religion, admitted as much in his seminal book on *The Future of an Illusion*. Personal testimonials and clergymen's sermons about religion's potential to relieve stress are too numerous to cite here. Religion is so commonly associated with stress that it is virtually a reflex to invoke it at moments of stress. Many images of religion and extreme stress spring to mind immediately, from foot-stomping spirituals of the segregation-era South to the footsteps of the death-row dweller listening to the last words of the seventy-first psalm to the prayers mumbled by chaplains for charging troops who face death on the front. We can even consider the fearlessness of the 9/11 suicide bombers who embraced their own death as (perverse) testimony to the power of faith.

Although not everyone finds relief in religion, there are some compelling sociological statistics supporting religion's overall ability to combat stress. It is well-established that people with strong personal religious beliefs and affiliations are less likely to commit suicide, which can be seen as the ultimate and most extreme response to stress. The fact that some Islamic extremists encouraged suicide missions, in spite of Islam's strong stance against suicide, is an aberration.

Philosophical Aspects

By positing the existence of a supernatural being who actively intervenes in the natural world and who has a plan for each individual human, religion provides an automatic antidote to the stress of being alone and awash in an unresponsive and uncaring universe. Philosophers and theologians alike note that existential angst and dread have plagued twentieth-century society, at least in the West. Ever since Nietzsche declared that "God is dead" as the nineteenth century ended, and as his own symptoms of neurosyphilis progressed, unwavering faith in the supernatural melted away and slowly but surely became the foremost source of stress. Only the lurking specter of a sudden nuclear holocaust overshadowed this stress. Pastoral pop psychologists tried to reverse the tide

that Nietzsche set into motion. Best-selling books, such as Paul Tillich's *Man Is Not Alone*, played on Nietzsche's angst-inducing assertion in its title and appealed to this angst. Similarly, film titles and themes recapitulate the reflexive tendency to call on religion in times of crisis. For instance, the film *God is My Co-Pilot* appeared during World War II. More veiled religious themes bubble to the surface during other times of stress. When the Great Depression cast its shadow, *Lost Horizon* evoked legends of Shangri-La, where Tibetan monks and Christian missionaries fused good works and good karma and reinfused human souls. Then, as the twentieth century came to a close, and as second millennium neared – at the very same time that information technology zoomed ahead and rocked standard channels of communication – religious imagery once again resurfaced in secular guise, this time in the form of angels. New Age angels, which were retrieved from Renaissance-era paintings, appeared on postage stamps.

Psychological Aspects

Antidote to aloneness, abandonment, and dependency

When psychoanalysts try to explain why a belief in the supernatural relieves stress, they look for more personal, rather than societal, explanations. The consistently controversial Freud claimed that a belief in God substitutes for the presence of an all-protective, albeit sometimes punitive, parent. According to such theories, religion recreates the reassuring world of dependency that an infant enjoys. The oceanic feeling of connectedness with the universe that mystics describe could be a way to return to the peacefulness and protectiveness of the womb, where an umbilical cord delivered never-ending nourishment and where amniotic fluid buffered the baby from unkind blows from the world around. Religious redemption concepts that revolve around the return to Eden can be compared to psychoanalytic fantasies about the return to the womb.

More contemporary neo-Freudian psychoanalytic thinkers, such as Karl Winnicott, emphasized the importance of separation-individuation as the critical step in psychological growth. Unlike more orthodox Freudians, who viewed religious reassurance as a sign of psychological immaturity and as an obstacle to self-actualization, theorists such as Winnicott felt that religious belief functions as a useful transitional object, much like a baby blanket or a teddy bear. Both remind the child of the parent's perpetual presence and assuage a child's subjective stress of abandonment during the parents' absence. There are many, many more psychoanalytic theories about the ways that religion relieves stress, each unique and interesting in

its own right and each as untestable by scientific techniques as the tenets of religion itself.

A more pragmatic and less theoretical take on religion as a surrogate dependency is found in the principles behind the Twelve-Step and Recovery Programs and Alcoholics Anonymous. These programs provide a strong social support system and also call on a Higher Power to relieve the psychological and physiological stress of alcohol withdrawal and as an aid in dealing with stresses that were previously ameliorated by addictions. Rather than admonishing their members for depending on this spiritual Higher Power, as more Freudian-influenced therapists did in the past, the Twelve-Step groups see spiritual dependency as far less harmful than chemical dependency. Such pro-spiritual approaches have gained increasing public and professional acceptance and have been adapted to the treatment of many other disorders.

Decreased sense of randomness and uncertainty

There are many other ways that religion relieves personal stress. Religion decreases the sense of randomness, uncertainty, and chaos in the world because it details the logic (or illogic) behind a world plan. It predicts or sometimes prophesies or, at the very least, attempts to explain those events that seem most inexplicable. In doing so, it creates a concept of stability that has been described as an ordered universe. Even religions that foretell the coming of adverse events in the future, such as an impending apocalypse, reincarnation, predestination, or bad karma, have the potential to offer partial relief from stress, simply because they help their members prepare themselves psychologically for adverse events. Providing explanations for events, even without providing a means for altering those events, is referred to as heuristics, and this is one of the most powerful psychological tools that religion possesses. Some critics of psychoanalysis say that its appeal also rests on its heuristic value and argue that unprovable psychoanalytic explanations provide reasons for behavior rather than remedies, in the same way that religion provides reasons for cosmic events and human nature.

Religions further relieve the stress of uncertainty by providing blueprints for behavior that can theoretically change the future. By prescribing prayer, penance, codes of charity, dietary laws, sacrificial rituals, or right thought, those religions reestablish a sense of personal control. More optimistic prophesies, and promises of paradise, confer hope and escape.

Cognitive coping techniques Above and beyond any theoretical parallels with psychoanalysis, many religions also provide specific cognitive techniques that are useful in coping with stress. For instance, the mere

act of acknowledging and articulating the experience of stress can quell some distress. Long before Freud discovered his talking cure, religious prayers and petitions provided collective voices for stress and distress. Hebrew psalms that begin with words such as "From the depths I called out unto Thee" poeticize an acute sense of anguish, whereas Christian recreations of the crucifixion scene dramatize the ordeal of Christ on the cross. These words and images are especially appealing to people who do not have access to other avenues of expression, or who prefer to deflect their own subjective sense of distress by focusing on more universal, cosmic, or collective stresses.

Role models for stress endurance Religious lore offers as role models people who withstood extreme stress and either surmounted that stress, were valued because of their ability to endure stress, or went on to fulfill higher purposes because of those stresses. The Christ-figure is the consummate example of this sort, but it is hardly the only one. Biblical stories about Jonah being swallowed by a whale, Noah's ability to withstand a flood, Daniel's survival in the fiery lion's den, and Job's endurance of the loss of his family and his health all reassure believers that there is a relief for stress or, if there is no immediate relief, that there is a reason or perhaps even a reward in another life. The martyrdom of Christian saints before their beatification, the Buddhist *jataka* stories about Prince Shakyamuni's wandering as a mendicant monk before he achieved enlightenment as he sat under the Bodhi tree, and the image of the Israelite tribes wandering through the desert for 40 years before entering the Land of Israel and acquiring their status as the chosen people are other examples of the pivotal role that stress endurance plays in religious themes.

Consolation, devaluation, and dissociation Some religions provide such a sense of consolation that they have been dubbed the religions of consolation. Christianity's contention that the meek will inherit the Earth reassures people that their this-worldly stress and suffering will be relieved by other-worldly rewards. The promises of future paradise made by prophetic religions dull the pain of the present and appeal to the impoverished, the downtrodden, and the psychologically stressed. Some religions offer so much consolation for contemporary stress and distress that they devalue the material world completely by undermining its ultimate importance or by teaching that the real world is but a delusion and no different from a dream. Buddhism's belief that the material world is nothing more than a delusion, or *maya*, is an extreme example of such transcendent thinking. The Hindu yogin's aspiration to a waking

state of dreamless sleep is another example of transcendence. Some psychotherapeutic techniques train patients to use similar techniques of detachment when confronted with stress-producing stimuli, although it cannot be overlooked that people who enter such dissociative states spontaneously and nonvolitionally develop serious difficulties in life.

Temporal and physical escapes from stress Even world-affirming religions, which affirm the importance of the material world, often offer temporary escape routes from daily stress. Religious holidays and religious services and other sacred times carve out stress-free time during the ordinary workweek and create an opportunity for rejuvenation. For those times when real-world stresses require even more relief than routine religious beliefs or rituals can confer, some religions offer physical as well as temporal retreats where food, clothing, and shelter are available, along with social support, structure, and spiritual exercises. Ashrams, yeshivas, monasteries, convents, and any number of other religious communities provide parallels to the retreats popular among certain Christian denominations. Such religious retreats not only legitimize the need for relief from stress, but also consecrate the choice to retreat from stress. Such religious retreats thereby provide participants with a renewed sense of self-worth, along with a sense of connectedness with others who share their belief system, and may even offer retraining in new vocations or avocations. Some retreats encourage members to contribute to society by doing good works or charity. The modern hospital movement evolved out of the monastic retreats in the Middle Ages, where people who originally sought relief for spiritual, physical, psychological ailments eventually provided care for others after their own recovery. In contrast, psychiatric rest cures and funny farms, which also offered retreats from the real world, stigmatize the participant, pathologize the process, and end social productivity. It is no wonder that religious retreats are often preferred over psychiatric treatment and that religion is often the first defense against stress.

Social Aspects

For some people, and for some religions, religion is a solitary matter and nothing but. For them, it is personal spirituality that matters most, with respect to stress relief and everything else. Although the title of William James's often-republished book is *The Varieties of Religious Experience*, in it James focused exclusively on religion that is experienced in solitude. Nevertheless, religion exists on a social as well as a personal level and acts to relieve social stress (or

produce stress) on both levels as well. By providing a social support network through their communal services and activities, coupled with a sense of collective identity and purpose, religious organizations can directly combat the stress of loneliness, displacement, and *anomie* that Emil Durkheim implicated in his early sociological studies of suicide.

Some religions provide material benefits, such as charity, lodging, employment, social services, and subsidized medical care, which can counteract the intense stresses of economic hardship and ill health and can complement the psychological consolation inherent in religious theory. Religious bureaucracies also offer alternative, and much appreciated, channels for personal and political expression, particularly when access to legitimate political clout is closed. Moreover, organized religion can become powerful enough to challenge the existing political and economic powers and bring about lasting and legitimate social and legal change.

Studies of the conversion process are especially illustrative of the importance of social forces and religion. It often comes as a surprise to people who are ideologically committed to religion to learn that it is the social sway of a religious group that influences individuals to adopt new religious ideas rather than the other way around. In other words, rather than experiencing a life-changing epiphany before converting, similar to the epiphany that the Gospels attributed to Saul of Tarsus on the road to Damascus, converts to new religions are more likely to follow a socially paved path to new religious insights. They accept more and more of the ideas of the group as they gain greater and greater acceptance into that group and as they become more reliant on group members for social support. The process of conversion is more likely to be gradual than sudden; in most people, behavior changes incrementally rather than dramatically. Nor does everyone who gets involved with a new religious group remain committed to that group. Of the many factors that correlate with an individual's long-term involvement with a new religion, one of the most important factors revolves around the role of stress. The more stress relief that an individual experiences at the time of joining a new religious group, the more likely that person is to remain a member of that group. Furthermore, it is the stress that individuals experience when distancing themselves from such groups that typically compels them to return to those groups.

Because it is well known that people who are already in a state of stress stand to achieve the greatest degree of stress relief from a new religion, some such religions make it a point to stress their newest members. Techniques such as sleep deprivation, diet

restriction, social isolation, overwork, enforced silence, sexual abstinence, or even physical or psychological threats make new recruits more receptive to the stress-relieving effects of the religion. Religions that rely on such insidious, quasi-coercive stress-inducing techniques are often denounced as cults and are disdained by nonmembers or former members. Such cultish religions predictably recruit in institutional settings, such as colleges, prisons, and retirement communities, where people are already in high stress states. Because such residents are pre-primed for proselytization, new religions have made major inroads in such places, at times to tragic ends.

It is the intense stress of prison life, rather than an earnest desire to reform or to atone their past acts, that propels some inmates to seek relief through religious conversion. Many ministries maintain an active presence in prisons because they recognize this potential. Sometimes, religious recruitment goes hand in hand with political indoctrination and can lead to involvement in militant religious factions. Many Black Muslims and Seven Percenters, including Malcolm X, traced their conversion to their incarceration. Yet, until 9/11 made the U.S. public more aware of this potential, there was little public opposition to religious recruitment in prisons. Most people assumed that religions strive to instill socially acceptable values that will substitute for criminal behavior, aid in rehabilitation and reentry into society, and thwart future incarceration. The recruitment of prisoners to a new religion was preferred over recruitment by antisocial prison gangs. However, in our post-9/11 world, we must consider the possibility that some extremist religions can instill antisocial attitudes and push some individuals into committing extreme acts.

In contrast, there has been a great public outcry about cult recruitment on college campuses, partly because some cultish religions have the opposite effect of prison-based cult religions. Rather than aiding the recruit's reentry into society, these cults isolate students from society and abort their attempts to achieve the status of other adults in society. Some cults cut off members' contact with families and friends, and cause severe stress in their relatives as a result. Although many legitimate religions were considered to be cults in their early stages – with Methodism being the most notable U.S. example – the mere fact that a small percentage of cults have been associated with mass suicide or homicide is enough to cause public concern and to stimulate psychiatric task forces to investigate these issues. The memories of 800 deaths in Jonestown, the loss of 19 lives in California's Heaven's Gate suicides, the subway poisonings by Japan's Aum Shinrikyo sect,

and the murder of a Hare Krishna defector in North Carolina tend to overshadow studies that show the psychological benefits of conversion in some individuals.

Somatic Aspects

Stress is as much a physiological response as a psychological one. Some religious rites use physical means to achieve higher spiritual states and alleviate both psychological and physiological stress in the process. The muscle stretching systems of yoga, the breathing exercises of Zen, and the controlled movements of Tai Chi are just a few examples of Eastern-influenced mind-body methods that gained popularity in the West. Some of these methods are now taught in continuing education courses sponsored by the American Psychiatric Association.

Although it is impossible to verify the existence of higher spiritual states, it is possible to measure changes in heart rate, respiration, galvanic skin response (sweating), pupil size, secretions of stress hormones such as cortisol or gastric acid, brain waves (through an electroencephalogram, EEG), and muscle tension in people performing those spiritual exercises. Internist Harold Benson's studies of cardiovascular effects of Transcendental Meditation and Tibetan Buddhist chanting appear in juried medical journals and in his popular paperback, *The Relaxation Response*. Japanese psychiatrist Tomio Hirai correlated the EEG and electromyogram (EMG) effects of both Zen meditation and Hindu yoga with reports of spiritual and psychological states and published his results in the curious book *Zen Meditation and Psychotherapy*. These works represent serious research, but there have also been many hyperbolic claims about the benefits of Eastern (and Western) religious systems, leading some professionals to dismiss any and all claims reflexively and prematurely. Recent scientific studies confirming the correlation between stress relief and specific religious rites suggest that both an open mind – and an open eye – can help us to appreciate confirmed the mind-body benefits of religion and also to avoid misleading claims and cults.

Quite the opposite of the calming meditative techniques of Eastern religions are the ecstatic dances, shaking, quaking, rocking, and rolling movement of some sects, which inspired the names Holy Rollers, Ranters, Ravers, Quakers, Shaking Quakers, and Shakers. Such intense activity presumably relieves stress through the same mechanisms that jogging and exercise help more secular devotees. The Dionysian dances of Classical Greece, described in Euripides' play about the Bacchae, were but one of many recurring manifestations of frenzied religious dancing that

serves a related function. Repetitive religious rituals in general are said to relieve stress as well.

Side Effects of Stress Relief

Religion's efficacy at relieving stress does not come without side effects. There are times when religion relieves stress so well that its practitioners are unaware of the demands of the real world and are unable to mount a defense against impending danger. Many social scientists have said that the religious devotion of African Americans shielded them from the pain and poverty of pre-Civil Rights America and delayed the adoption of more appropriate political tactics. Similarly, the Tibetan practice of sending one-third of its youth to Buddhist monasteries left the country defenseless against the Chinese invaders who destroyed temples, massacred monks and nuns, and sent their religious leaders into exile. Some secular Zionists claimed that the insulated and self-satisfied religious infrastructure of some eastern European Jewish communities obscured their awareness of the deadly fate that awaited Jews in Hitler's death camps. An analogous U.S. tragedy occurred when Native American warriors went into battle unarmed, believing that their Ghost Dance ritual would protect them from the guns and arrows of approaching armies. Marx and Engels blamed the mystical and occasionally bizarre religious belief of Russian orthodoxy and schismatics for numbing Russian reactions to the material exploitation by the capitalists and the Czars. This observation prompted Marx to coin his oft-quoted characterization of religion as "the opiate of the masses."

Religion as a Cause of Stress

As effective as religion can be at relieving stress, it can also produce stress. Threats of an afterlife full of hellfire and brimstone or of an impending apocalypse that will destroy the world are obvious stress-producers. On a more subtle level are the many moralistic demands and behavioral codes made by religion, which are often difficult to live up to and, thus, tend to leave some practitioners in a near-constant state of imperfection and incompleteness. Some practitioners adopt even more zealous beliefs and behavior in order to avoid that stress, in an ever spiraling pattern. Skeptics such as psychiatrist John Sargeant observed that some charismatic religions exploit this tandem stress relief–stress production effect when they proselytize and compared this push–pull effect of religion to behavioral conditioning, more nefarious methods of mind control and brainwashing, and even drug addiction.

For sure, religion-induced stress is not limited to perceived threats, nor is it confined to the personal psyche. In spite of its promises of eternal peace, organized religion has indeed injected some of the most realistic threats the world has ever witnessed. The Inquisition, the Crusades, and the wars of religion are but a few testimonies to reality-based stresses posed by religion in the past. Such stresses persist to the present day through suicide cults such as the California-based Heaven's Gate, Islamic terrorist attacks on the World Trade Center, the biological-weapon-wielding Aum Shinrikyo in Japan, the Hindu–Muslim–Sikh conflicts in an atomic-bomb-armed India, the religious-ethnic conflicts of the Balkans that set the stage for World War I, and right-wing religious assassinations in Jerusalem, to name just a few. Although some religions aspire to the day that "the lion will lie down with the lamb," that day has not yet arrived. Religion has been, and probably always will be, as intimately associated with the stress of war and violence as with the proverbial love and peace that it promises. Rising religious fundamentalism promises to produce more political and personal stresses for individuals and for the world at large. At the same time, the religions of reassurance will provide personal stress relief for individuals, creating a never-ending seesaw.

Religion as a Correlate of Stress

The correlation between the rapid rise of new and sometimes radical religious movements and the degree of social stress is nothing less than remarkable; it is cataloged in Norman Cohn's classic *Pursuit of the Millennium* and in his more recent *Chaos, Cosmos, and the World to Come*. A more recent book, *Radical Religion in America*, zeros in on extreme religious schisms that have arisen since 1970, during the times of high stress that followed the social turbulence of the 1960s. It is noteworthy that psychoanalysis, a once-esteemed and all-embracing psychiatric treatment that survives as a mere shadow of its former self, has also been accused of being a cult and of inducing a cultlike devotion that resembles religion more than science. Note that psychoanalysis's popularity peaked in the 1950s, during the times of high stress that followed World War II.

Concerns of Christians and Others after 9/11

Glossary

<i>9/11</i>	September 11, 2001, the day that the World Trade Center was destroyed and the Pentagon was attacked by organized conspirators led in absentia by Osama Bin Laden.
<i>Islam</i>	A prophetic religion that is based on the teachings of the prophet Mohammad, as recorded in the Koran. (Also called Mohammadanism.) Followers of Islam are known as Muslims and may be of any race or ethnicity and may live on any continent. Many, but not all, Muslims are also Arabs.
<i>Posttraumatic stress disorder (PTSD)</i>	A constellation of symptoms that occur after experiencing or witnessing a life-threatening episode. People with PTSD reexperience the original trauma through nightmares or flashbacks and feel detached or numb in daily life.

World Trade Center (WTC)

A complex of office buildings (also known as the Twin Towers after the two tallest buildings) located in lower Manhattan, New York City, that housed 40,000–60,000 workers. It was destroyed on September 11, 2001 (9/11), and the site where the WTC previously stood came to be known as Ground Zero. A religious and political belief that the political state of Israel is the Jewish homeland. Most (but not all) religious Jews are Zionists. Some secular Jews are Zionists, and many secular Jews are not Zionists. There are many different degrees of Zionism.

Zionism

An association between stress and religion has always existed, long before September 11, 2001, came to be known as 9/11 and long before the WTC was destroyed. Before 9/11, religion was most often seen as a cure for stress, but it could also be conceived of as a cause of stress and was certainly recognized as a correlate of stress. But on 9/11, the relative importance of those associations shifted. For most people in the United States, and especially for people who lived and worked in and near New York, religion suddenly shifted to being a serious source of stress. In fact, some very preliminary studies showed that people who were most religious were more likely to experience more stress after 9/11, although the reverse is usually true. In general, religious belief and affiliation offer protection against stress, but the reasons why

religion failed to protect against 9/11-related stress will become obvious during our discussion.

The Who, What, Where, How, and Why of 9/11

What was 9/11, and what made that day so significant to Americans in general and to New Yorkers in particular? On that day, the WTC was destroyed by young Islamic suicide bombers who flew two hijacked airplanes into each of the Twin Towers. At nearly the same time, another hijacked plane hit the Pentagon in Washington, D.C. A fourth passenger plane, bound for San Francisco, was also hijacked, but was commandeered by passengers and diverted from its target destination. That plane crashed outside Pittsburgh and claimed far fewer lives than it was intended to. Each of these events was part of a well-orchestrated and partly successful conspiracy to fell the United States because these Muslim extremists led by Osama bin Laden viewed the United States as an aider and abettor of Zionists who controlled the state of Israel. It should be noted, however, that this Tuesday morning attack on the WTC was not the first. Several years earlier, a van containing a bomb exploded in the WTC parking lot, killing six people and causing commercial chaos in subway-level shops; this culminated in the conviction of a blind sheikh who led this militant Islamic sect.

Some 2000 lives were lost during the second WTC attack on 9/11. Several hundred others died in the Washington area. None of the passengers aboard the hijacked planes survived. Although citizens of many cities, indeed, many countries, were affected by the tragic events of that day, 9/11 was most closely associated with New York City after the silhouettes of the WTC's Twin Towers vanished from the city skyline.

Situated in downtown Manhattan, near New York City's financial district and the world-famous Wall Street, the WTC also impacted ordinary New Yorkers who lived nearby. Those people were not necessarily involved in the financial or insurance or communications businesses that were centered in the WTC. Some New Jersey bedroom communities, short commutes from the WTC, were also impacted after dozens of their residents who worked in the Towers died that day.

The WTC was close to the bustling streets of Chinatown, a mecca for tourists and the culturally curious and home to long-time residents, recent arrivals, and legal and illegal immigrants from mainland China, Taiwan, Hong Kong, Vietnam, and Malaysia. Buddhists, Christians, Catholics, Confucians, Taoists, and Chinese ancestor worshipers coexist on the streets of Chinatown and often intermingle within a single family unit united by its shared Chinese

ancestry but not split by religious affiliation, as Western families often are. The once-lively Little Italy was also within walking distance of the WTC, as was the historically Jewish Lower East Side. In Little Italy, festivals named for regional Roman Catholic saints (such as San Gennaro) rose beyond their religious origins and attracted carnival-loving crowds of all faiths. It was to the Lower East Side, nostalgically known as Delancey Street, that poverty-stricken Jews fled the pogroms at the turn of the twentieth century. They turned their pushcarts into a sprawling Sunday shopping district that gradually gave way to trendy clubs with outrageous names like Lansky Lounge. The once-grand synagogues built by struggling immigrants were often in need of restoration because younger generations abandoned their grandparents' turn-of-the-century terrain and fled to suburbia. The Yiddish theaters that once lined Second Avenue below Fourteenth Street were now reduced to engraved copper stepping-stones that were embedded in sidewalks, engraved with names of yesteryears' Yiddish-speaking stars.

The largely Hispanic neighborhood of Loisada, or Alphabet City, was also a healthy walk from WTC, even if it was not near enough for lunch. Dotted with small Catholic churches, Pentecostal centers, *espirismo* storefronts, and even some *santeria* supply shops, this section was more religiously diverse than might be expected. The few blocks that were left of what were once, respectively, Little Poland and Little Ukraine lay slightly to the west of Loisada and due north of the Twin Towers, and were home to ornate Orthodox churches and even some shops catering to neo-pagan practitioners. Little India, which should rightfully have been called Little Bangladesh because its restaurateurs actually came from Muslim country of Bangladesh, was caddy-corner from Little Ukraine. And so on and so forth.

South Street Seaport, an old-time fish market that had been transformed into a mall-like tourist attraction, was an after-work refuge, replete with busy bars, shops, and eateries. Tribeca was a newly minted, mostly loft-living community on the lower west side of Manhattan; pricey, arty Soho lay a little to the east of Tribeca and the Towers. Battery Park City, with its combination of luxury condos and subsidized housing, was also a stone's throw away and was populated by young families in need of affordable housing and by financial firms that needed crash apartments for out-of-town deal makers and overnights. The West Village was not too far away either, with its authors, artists, and actors and its ever-active gay presence, which survived and thrived in spite of the devastation of the AIDS epidemic. The East Village, which was not quite as close

to the WTC as the West Village, was home to students, musicians, aspirants of all sorts, and also addicts, to judge by the reports of drug-related arrests. Several colleges and universities dotted the lower Manhattan landscape as well, including New York University.

Paradoxes about Post-9/11 Stress, Suicide, and Religion

There was a reason why we have delved into the details of these different downtown neighborhoods and business districts. We need to understand who lived downtown, why they were affected by 9/11, and why religion impacted some more than others. Studies have shown that the closer a person lived to Ground Zero, where the WTC once stood, the greater his or her chance of developing PTSD. That finding is not so surprising, considering how devastated the landscape was and how disturbing it was to view the carnage on a day-to-day basis and to smell smoldering flesh for weeks or maybe months later. What was surprising was that some studies showed that people with strong religious beliefs were more likely, not less likely, to experience stress post-9/11, even though religion ordinarily provides protection against stress. There were reasons why religion produced stress in this situation.

Other surprises awaited researchers after 9/11. Significantly, it turned out that people who received emergency debriefing were more likely, not less likely, to suffer long-lasting psychological symptoms of PTSD. It is now believed that rehearsing the traumatic event consolidated bad memories and made them more permanent than they might have been had the memories simply been allowed to fade away over time. An even bigger surprise concerned the prevalence of PTSD overall; post-9/11 PTSD was not nearly as widespread as first predicted.

Perhaps the biggest surprise overall concerned the role that religion played as a promoter of, rather than a protector against, suicide. Muslims, who ordinarily oppose suicide, might have even more reason for such surprise. Before we examine any specific associations between religion and suicide, let us look at some general associations between stress and religion.

Religion is often sought out in times of stress. It typically acts as a psychological salve. Repeatedly, religion has been shown to diminish the chances of completed suicide, which is the ultimate measurement of stress's effects. New religions are also known to thrive during times of social stress; recruitment to cults is especially successful during times of rapid social change. Moreover, religious participation generally decreases both criminal activity and criminal

recidivism (although high-profile exceptions to this trend have admittedly come to light).

Yet the events during and after 9/11 contradicted some of these basic assumptions (and I deliberately used the word assumptions because some of these givens about religion are not necessarily historically factual). For one thing, the mere fact that the suicide bombers committed both suicide – and homicide! – in the name of religion seems to stand established wisdom on its head. After all, study after study shows that religious faith and affiliation protect people from suicide and help people through severe depression, financial devastation, even grave and disabling illness. Religion as a generic concept is supposed to instill a reverence for life, not a disregard for life (although some Eastern religions devalue daily life to the point that they dismiss everyday existence as *maya*, or illusion, and some fundamentalist religious sects place more value on the heavenly afterlife rather than on the earthly this-life).

Yet here was a situation in which the strong religious beliefs of the suicide bombers not only did not protect them from suicide but actually pushed them to suicide. Moreover, their religious belief promoted not only suicide but also homicide – and promoted not just homicide but mass homicide. On the surface, the bombers' behavior appears paradoxical. No wonder some studies showed that people with strong religious beliefs felt more stressed after 9/11 than those with lesser religious commitment. Their confidence in the protective effect of religion was challenged. Any preexisting assumptions about the automatic ability of religion to counteract impulses to hurt oneself or others could no longer be accepted as absolute fact.

If we hypothesize that at least some of the people with strong religious adherence had gravitated to religion because they needed an extra buffer against stress in the first place, then it becomes even easier to appreciate why many felt more stressed after the 9/11 suicide attacks. If their psychological foundations were already shaky, but were buttressed by religious belief that now wobbled, then they would feel shakier still. They might need to distance themselves from the perpetrator religion (Islam), to prove that their own religion still provided them protection. It would be to their psychological advantage to deride Islam at face value, to draw a distinction between their own religion and Islam, and even to wage war against Muslims in order to protect their own psychological turf and to fortify their own mental foundation.

To understand the motives of these Muslim suicide bombers, we must realize that they acted on the earnest belief that they would earn themselves and their

families eternal paradise for their valiant acts of self-sacrifice. That reward system stands in direct contradiction to the hellfire and brimstone that presumably awaits devout Christians who choose suicide. The social prestige provided by those Islamic suicides is also the polar opposite of the social ostracism faced by Jewish families whose relatives elect to suicide. Because Jews who commit suicide cannot be buried in a Jewish cemetery, their survivors are deprived of the comfort of a collective mourning ritual, and the individual is deprived of an identity and a commemoration after death.

However, it should be said that 9/11 was by no means the first time that suicide was committed in the name of religion. Nor was Islam the first religion to encourage suicide in the name of faith. Christ's willing self-sacrifice on the cross could arguably be said to be a sort of self-accepted suicide. It is less controversial to claim that the desert saints who starved to death in the third and fourth centuries were also committing suiciding in the name of faith. Many Christian martyrs have been beatified because of their willingness to endure torture unto death in the name of religion. The Hindu *sati*, a cultural *cum* religious rite that requires the widow to climb on to the funeral pyre of her deceased husband and to join him in cremation and reincarnation, was a once-respected (but now suspect) religious rite of self-sacrifice. Jews who chose suicide over surrender at mountaintop fortress of Masada or who refused to convert to Christianity when the Spaniards offered them a choice between the cross or the Inquisition could be said to have chosen suicide, albeit under coercion. This was quite different from the Muslim suicide volunteers who went to their deaths willingly and equally willingly agreed to take the lives of many others.

Suicide through self-starvation is an acceptable, even respectable, end for some ascetic sects of Jains in India. In the Middle Ages, the Cathars practiced self-starvation as a religious rite. And let us not forget the soldiers who volunteered to serve in wars based on religion knowing that they might not survive the battle but believing in the utility of their self-sacrifice.

9/11 challenged the standard associations between stress and religion in other important ways as well. As previously mentioned, recruitment to new religions or cults typically peaks at times of social stress, as does religious involvement in general. But there is no evidence that such a trend took place in the wake of 9/11 because of very specific interventions. If anything, recruitment to psychiatric treatment peaked instead, as prevention efforts to avert the predicted outbreak of PTSD diverted interest away from religion and into more mainstream therapeutic approaches. Public

health and social service organizations made massive outreach efforts in the downtown area. Emergency debriefing stations were set up in lobbies in lower Manhattan, where residents were informed about both public and private psychiatric services. The Red Cross subsidized psychiatric treatment, even for those who could otherwise afford it. Posters recommending mental health care appeared in subway cars and at bus stops and reminded commuters that mental health care was not only easily available but was also readily affordable. As it turned out, these seat-of-the-pants psychiatric treatments did not accomplish what they purported and now seem to have increased the stress symptoms and PTSD. But they may have prevented religious-cult recruitment in an otherwise susceptible population.

For anyone who came of age at a time when public service announcements reminded Americans that the "family that prays together stays together" and when religion was the first referral made to someone suffering from stress or distress, seeing these subway posters was startling. These posters signaled a significant shift in social values as well as in clinical care. We might say that making a first-line recommendation for psychiatric care, rather than for religious rituals, was a sure sign that psychiatric treatment had finally come of age and was de-stigmatized enough to appear in public places outside of student counseling services.

Another explanation for the strong emphasis on mental health and PTSD in the immediate aftermath of 9/11 may have reflected the professional make-up of New York City. New York City is home to an unusually high number of mental health and social service professionals whose services are available at a moment's notice. Plus, psychotropic medications had become increasingly available and acceptable during the decade that preceded 9/11. The public had heard about the benefits of Prozac, and about its hazards as well, and had voted for the former. Unfortunately, it took approximately 2 years for researchers to realize that the mental health-mediated debriefings meant to prevent PTSD had actually increased its occurrence. In contrast, those who were treated with medications that decreased physiological reactions fared better.

We might hypothesize that astute politicians and public health officials had an even greater goal when they choose to promote mental health treatment rather than religion to assuage stress. City bureaucrats, who are acutely aware of the intense role that religion plays in politics at any given time, may have realized that an excessive emphasis on religion could polarize people even more at this crucial time. Such

polarization could create serious social unrest, catalyze riots, trigger interreligious rifts, and provoke other unpredictable reactions. Perhaps someone realized that it was socially safer, if not clinically wiser, to shift the focus to universal psychiatric approaches and to deflect attention from particularistic religious relief.

Even though religion was not recommended as a first-line antidote for post-9/11 stress, we would be hard-pressed to deny the daunting impact of religion-related stress. Admittedly, we would be equally hard-pressed to find complete and accurate data on this topic at this early date, and so we must make do with speculation and hypotheses, seeded by anecdotal reports from the *New York Times* and garnered from personal clinical experiences.

Muslims and Mental Health after 9/11

Most obviously, we expect that Muslims would be affected most dramatically by the events of 9/11, not just because 9/11 was perpetrated by Muslims who acted against other Americans in the name of their faith but also because of the repercussions against Muslims (and against those who were mistaken for Muslims). At this point, it is important to point out that many different people from many different countries and from many different ethnic groups embrace Islam around the world and that the choices made by the suicide bombers were the choices made by but a few members of a multimillion-member religion. Yet all American-based Muslims were forced to face scrutiny by the American public. Many were subjected to police searches, involuntary incarceration, or automatic deportations, all of which caused stress.

Once the United States declared war on Iraq, American Muslims faced further stress, regardless of their personal political persuasions or religion affiliations. There were some similarities to the indignities endured by Japanese Americans during World War II, when their allegiance to the United States was suspect after Japan bombed Pearl Harbor, to the point that even U.S. citizens were moved out of their homes and resettled in closely guarded camps. Because Muslim Americans are sometimes (but certainly not always) identifiable through physical appearance or religious garb or Mideastern surnames, almost any Muslim can become an easy target of suspicion, discrimination, or outright abuse. Guilt through association can cause an assumption of guilt.

People who are in the United States on a student visa or a J-1 visa (as many physicians in training are)

also carry legal documents that identify their country of origin. It would not be surprising if stress-related disorders increased among Muslims after 9/11, but it is not known with certainty if this actually occurred. The U.S. medical literature is strikingly devoid of studies on this subject at the time of this writing. In fact, it is doubtful that the full extent of the medical or mental health effects on Muslims will ever be known with certainty. It is likely that many Muslims, especially those who are working or studying in the United States on revokable visas, will avoid treatment altogether for fear of calling attention to themselves and risking being reported to the authorities or of appearing to be less qualified to compete in the work or educational arenas that influence their visas. It is probable that Muslims whose immigration papers are not complete or perfect will follow the paths taken by other illegal immigrants in the United States and will also be left uncounted and untreated by the official U.S. health-care system.

Furthermore, it is not clear whether psychiatric symptoms alone, such as stress, anxiety, or insomnia, could accurately measure the distress experienced by this very diverse religious group, whose members come from a wide variety of cultures, educational backgrounds, and countries of origin, and who speak many different languages. Some cultural groups do not express distress in psychological terms but prefer physical descriptions instead, sometimes complaining of dizziness, sleep problems, or vague aches and pains. Even people who are aware of psychiatric symptoms per se are still not immune to medical illnesses that increase in the presence of psychological or social stress. Cardiovascular and cerebrovascular events are notorious for their responsiveness to stress, as are some gastrointestinal diseases, autoimmune disorders, and even neurological symptoms.

In many instances, increases in drug and alcohol use are more accurate and immediate indicators of stress than are purely psychological symptoms and must be studied with as much diligence as medical or psychiatric symptoms. Alcohol consumption in New York City skyrocketed after 9/11, especially among women, as both medical statistics and bar revenues attested. But it is important to be aware of the baseline alcohol and drug consumption of any particular culture before determining if there has been a significant increase in use. For instance, Islam (apart from renegade Sufi mystics) generally prohibits alcohol. Therefore, even a modest increase in alcohol consumption in Muslims after 9/11 carries very serious clinical implications and cannot be meaningfully compared to increases that occurred in religious or ethnic groups that do not outlaw alcohol. On the

other hand, some Islamic cultures permit public marihuana use or even the social consumption of opium-based tea, although these activities are outlawed in the United States.

Although I cannot make claims to any population-based data on the use of psychiatric services by Muslims at this time, I can comment on recent trends in my own private practice in downtown Manhattan. Two distinctive gender-based trends emerged among Muslims.

First, there was a sudden surge in foreign-born Muslim males living in the United States on student visas who requested outpatient treatment for anxiety, insomnia, concentration problems, and vague perceptions of persecution by peers and co-workers. In some instances, patients needed an official return-to-work clearance, which they thought could be completed in a single visit. At other times, people who had longstanding behavior issues that could easily have been identified by college advisors much earlier were suddenly sent for psychiatric evaluations.

In each instance, these men were asked specifically if they thought that their new onset of psychiatric problems resulted from religious or cultural issues. If relevant, each was asked if he felt that the school or employer's request for psychiatric clearance was prompted by increased security concerns that were specific to Muslims. In each instance, the prospective patient denied any such association, but, in one case, the patient refused to fill out a form that inquired about native language, religion, and culture and made a point of stating that he did not consider religion to be relevant. When told that many patients, particularly college students, do not complete that section, he continued to insist that doctors do not need to know his religion.

Denial is not unusual in psychiatric practice, and a patient's repeated denial of the importance of an otherwise important issue can lead to a fertile investigation of psychological conflicts. Such denial usually takes place within the psychiatric interview itself and is addressed, often quite productively, during the therapy session. What was unusual in this situation was the prospective patient's repeated refusal to fill out standard medical history forms prior to the appointment.

Occasionally, the private outpatient psychiatrist encounters a paranoid patient who refuses to complete paperwork at the time of the first interview, but, more commonly, someone who is that paranoid avoids an appointment altogether and is brought to an institutional setting involuntarily. Moreover, pure paranoid patients typically show other observable signs of paranoia; their eyes scan the room and they sit near the door, if they sit down at all. They may refuse to enter

enclosed spaces in the first place (which comes as welcome relief to the psychiatrist, who is equally ill-at-ease in being with a potentially volatile paranoid person).

Yet, in the situations described here, the Muslim men did not exhibit other observable signs of paranoia. Their previous social functioning prior to the onset of their psychiatric symptoms was definitely not suggestive of serious preexisting psychiatric illness. In each instance, these men were well-educated and performed well in the past, making it unlikely that their circumscribed suspicions about filling out forms was part and parcel of more global paranoia and appeared to be based on legitimate fears about incarceration or deportation or the loss of his job or student status or visas required for school or work, even though each denied this possibility. This paranoic behavior can be compared to the guardedness and evasiveness seen in some African American men who have had unpleasant experiences with legal authorities in the past.

Second, I noted an even greater increase in the number of Muslim American women seeking psychiatric treatment, albeit for very different reasons. These women typically sought treatment because of stress brought on by family conflicts that arose as a result of their defiance of the gender-role restrictions traditional in Muslim families. In some cases, romantic involvements with non-Muslim men had already caused serious family rifts and threatened the patient with the loss of both family and financial support. It is difficult, and also probably inaccurate, to attribute these situations solely to the aftershocks of 9/11. It is much more likely that Americanization in general was responsible for rattling the religious traditions of these new immigrants, just as Americanization and the increased social choices afforded by U.S. society have shaken the foundations of nearly every ethnic group that arrived on U.S. shores. Still, I wonder if the Muslim-mediated suicide bombings of 9/11 shook the faith of at least some Muslim women and gave them tacit permission to question the overall correctness of preexisting, previously unquestionable cultural and religious traditions. Alternatively, perhaps the widespread publicity about psychiatric treatment that came in the wake of 9/11 also made these women aware of the availability of secular psychiatric treatment for personal stress.

Jewish Issues Associated with 9/11 Stress

Last but not least, let me turn to specific stresses experienced by some Jews after 9/11. Although there are no studies to date that show that New York City Jews were

at increased risk for post-9/11 PTSD, there are reasons why Jews might experience different stresses than other religious groups. For one thing, some Muslim extremists said that they had bombed the United States specifically because of its support for Zionists in Israel. Moreover, some semiofficial spokespeople stated that they had targeted New York City in particular not just because of its centrality to the financial and communications industries but because of its disproportionately high Jewish population. Such extremists link all Jews to extremist Zionists, regardless of their personal political persuasions.

Jews might feel themselves targeted by the Muslim extremists, but they might also have residual PTSD because of personal or cultural connections to the Holocaust, when 6 million Jews perished at the hands of the Nazis. Those who smelled the burning bodies in the WTC – as did anyone who lived downtown, often for months afterward – typically compared the scene to the crematoria where Jewish bodies were burned en masse after being gassed in places such as Auschwitz. Such scents were described in detail in accounts by Holocaust survivors. Ironically, 2000 people perished in a single day at WTC on 9/11. That very same number – 2000 – was gassed every single day at Auschwitz when the ovens were at their peak performance. This strange synchronicity did not go unnoticed by those who knew the details of the Holocaust, and it served only to highlight the horrors of the Holocaust and to reopen old wounds that refused to heal.

Some Jews were pretraumatized because friends or relatives had been hurt or killed during recurrent terrorist attacks in Israel. Many felt personally threatened when they saw that the same terror could take place on supposedly safe U.S. soil. Among Jews who were familiar with Jewish history, 9/11 was compared to Kristallnacht, the day that marked the beginning of the Holocaust, when Jewish shops were shattered by Nazi storm troopers in a foreshadowing of the horror that was to come a few years later. The fact that this was the second, not the first, attack on the WTC was used to fortify the comparisons with Kristallnacht.

It is curious that a disproportionate number of Jews lived in the expansive Grand Street Co-ops in lower Manhattan. It is also curious that New York University, a university often identified as having a high proportion of Jewish students, dots downtown Manhattan. With its sprawling campuses and dormitories, New York University spans the area from the Seaport to Fifteenth Street, with some dorm rooms overlooking Ground Zero. It is possible that the presence of these ethnic and religious populations skewed statistics and influenced the high rate of PTSD among

those who lived near Ground Zero. A more detailed demographic study of post-9/11 stress syndromes could clarify these possibilities.

Concerns of Christians and Others after 9/11

Is worth noting that members of some religions and ethnic groups became Muslims by proxy and were subjected to tauntings and even beatings because they were mistaken for Muslims. Turban-wearing Sikhs and Jains from the Indian subcontinent were targeted by aggressive youths in the days after the bombings and some were seriously injured. It is conceivable that people who practice many other religions but who appear to be of Mideastern or Muslim origin realized that they were at risk and so have suffered increased stress since 9/11.

It is likely that even all-American Christians also suffered from religion-related stress after 9/11, simply because most Americans like to think of themselves as religiously tolerant and become uneasy when religious prejudices are provoked, as they were by the events of 9/11. Let us not forget that the United States was founded for the expressed purpose of freedom of religion. When religion-inspired acts such as the terrorist bombings and hijackings of 9/11 threaten to make folly of this basic American freedom, everyone, regardless of his or her religion, feels stress.

In summary, Although there is much that remains uncertain about the overall impact of 9/11, both with respect to religion and stress, and to its many other ramifications, some things are certain. For one thing, 9/11 brought renewed attention to religion and its role in both promoting and protecting against stress. Unlike the Oklahoma bombing, which was strictly secular, this mass murder was intimately linked to religion and always will be, regardless of what is revealed about the individual bombers' personal psychologies in the future. This sad event serves as a reminder that the age-old association between stress and religion cannot be put on the shelf and relegated to the past; it is very much a part of the present. The subject of stress and religion is as relevant to the twenty-first century as it was to the first century CE.

Glossary

BrdU

(5-Bromo-2'-deoxyuridine)

A thymidine analog that is incorporated into the DNA of a dividing progenitor cell during the S phase. Fully differentiated neurons do not divide and cannot integrate the label. Depending on the survival time after application, BrdU is a marker of proliferating cells (short survival time) and their progeny (longer survival time). BrdU labeling is a nonisotopic immunocytochemical method.

Early Ideas about the Stress Response

When Selye formulated his stress theory approximately 70 years ago, stress was thought to have a

merely endocrine character, and noxious stimuli of physical or chemical nature were the primary stressors discussed. However, subsequent research demonstrated that stress-induced activation of the endocrine system leads to increased release of glucocorticoids (cortisol in primates including humans, corticosterone in rodents) from the adrenal cortex and that these peripheral stress hormones also profoundly influence brain function. Moreover, stress also increases the activity of the sympathetic nervous system to enhance release of norepinephrine from peripheral nerve endings. In addition, stress modulates the activities of, for example, central nervous monoaminergic circuits. These have diverse effects on many brain cells. Great progress has been made in the understanding of the biology of stress reactions and the neurobiological alterations that occur as a consequence of exposure to challenging events in the environment.

Stress Circuits

One of the most intensively investigated stress circuits is the limbic-hypothalamic-pituitary-adrenocortical (LHPA) system, which determines the magnitude and duration of hormonal, neural, and behavioral reactions to stressful experiences. The LHPA system combines both brain and endocrine components and can be regarded as a classic neuroendocrine circuit that integrates cognitive, emotional, neuroendocrine, and autonomic inputs. It consists of the primary brain regions that process emotional information, the limbic system and the hypothalamus, as well as pituitary and adrenal glands as endocrine organs. In concert with other neurohormonal actions such as stimulation of the adrenomedullary system (release of adrenaline from the adrenal medulla), LHPA activation leads to an increased release of corticosteroid hormones from the adrenal cortex into the bloodstream. These

steroid hormones are potent modulators of cell physiology, mood, and behavior and serve both to alert the organism to an environmental or physiological challenge and to defend its homeostasis.

Within the LHPA system, the hippocampus plays a central role. This brain structure has a high density of corticosteroid receptors and modulates glucocorticoid release from the adrenal cortex via a negative feedback loop exerting inhibitory effects on the LHPA axis. In addition to its intimate involvement in neuroendocrine regulation, the hippocampus plays an important role in emotional processing and in key aspects of learning and memory. While short-term activation of the LHPA system is essential for vital functions, constant hyperactivity of the circuit results in chronically elevated glucocorticoids, a maladaptive and potentially neuropathological condition. As demonstrated in animal studies, chronic stress leads to an impairment of the negative feedback control mechanism of corticosteroid release from the adrenal cortex, partly because of a reduced expression of hippocampal corticoid receptors.

Activation of Brain Systems

Stress does not have a global effect on all brain areas. Rather, depending on the type of stressor, different neuronal circuits are activated. Limbic brain regions comprising, for example, the hippocampus and amygdala as well as the prefrontal cortex are sensitive to stressors such as restraint or anxiogenic external stimuli, for example, a novel environment. Common to these stressors is the fact that they require, prior to initiation or inhibition of the stress response, a central nervous processing of information coming from different sensory organs. This information processing involves limbic and cortical regions, and its outcome depends on previous experience. In contrast, physiological threats such as exposure to ether result in a direct activation of efferent visceral pathways, in part mediated by the paraventricular nucleus of the hypothalamus. In this case, the rapid activation of brain stem and hypothalamus circumvents cognitive-emotional processing via the higher brain regions.

The intraneuronal communication that finally leads to the stress reaction is brought about by neurotransmitter systems. Rapid neuronal responses to stress are elicited by, for example, glutamate (an excitatory neurotransmitter) and GABA (γ -aminobutyric acid, an inhibitory neurotransmitter). These modulators act on specific receptors and ion channels in neuronal membranes to directly control neuronal firing. This fast neurotransmission is modulated by slow-acting neurotransmitters such as the monoamines (for example, the catecholamines dopamine, norepinephrine,

and epinephrine and the indolamine serotonin). Activation of brain monoamine systems is a major component of the stress response, and turnover of monoamines is increased during stressful experiences. Stress-induced alterations in the monoamine system are regarded as the basis for stress-related behavior and are of special interest because the hyperactivity of catecholaminergic and serotonergic neurons that occurs during stress may induce an imbalance between the different neurotransmitter systems. This imbalance may contribute to psychopathologies such as major depression.

Another example of substances that modulate neuronal activity and are involved in mediation of stress responses are neuropeptides, for example corticotropin-releasing hormone (CRH). This is thought to play a major role in the stress response. Neuropeptides as well as monoamines exert their actions via specific receptors located in the membranes of neurons. Some of these receptors are also found in glia cells. Many of these receptors belong to the family of G-protein-coupled receptors (GPCRs) that are linked to intracellular second messenger systems via guanosine 5'-triphosphate (GTP)-binding proteins. The intracellular signal transduction pathways that are regulated by GPCRs bring about many of the short- and long-term effects of stress on neuronal activity and regulate most aspects of neuronal functioning, including metabolism and gene expression. Thus, intracellular signal transduction systems play a key role with respect to stress-mediated regulation of neuronal functioning and structure, and, on the cellular level, they represent the first step of a cascade of events in the brain that leads to changes in neural cells, including alterations in gene transcription and morphology of neurons. Adverse effects of stress are supposed to result partly from (1) sustained activation or inhibition of certain neurotransmitter systems and intracellular pathways and/or (2) chronic exposure to neuroactive substances such as the glucocorticoids. These steroid hormones interact with intracellular receptors, forming complexes that bind to specific sites on DNA to regulate transcription.

Structural Plasticity of the Adult Brain

Approximately a century ago, it was finally established that the brain consists of neurons and glia (neural cells) rather than being a continuous syncytium. Thereafter, a rather static view of the brain prevailed. It was thought that electrical and chemical information was processed by fixed neuronal circuits. Ramon y Cajal stated that "in adult centers the nerve paths are something fixed, ended, immutable. Everything may die, nothing may be regenerated" (Cajal

1928, p. 750). However, in recent years, this view has been gradually revised on the basis of studies demonstrating that neuronal circuits and connections between cells in the brain are subject to lifelong modifications and reorganizations. An impressive example of the consequences of alterations in sensory inputs and changes in circulating hormones comes from research using ground squirrels. In these hibernating animals, synaptic contacts of mossy fibers with CA3 hippocampal pyramidal neurons are altered in many aspects of their structure during different stages of the torpor–activity cycle. This clearly demonstrates the capacity of the adult brain to adjust its neuronal circuits to altered hormonal and/or sensory input. Based on such findings, it was hypothesized that similar structural modifications may also occur during stressful life events when hormonal levels are altered (for example, elevated glucocorticoids, reduced gonadal steroids) and when sensory input is changed. It has transpired that this view is accurate.

This ability of the brain to perform functionally relevant adaptations following various challenges is called plasticity. Neuronal plasticity is absolutely mandatory for adequate functioning of an individual in a continuously changing environment. The dynamic processes of neuroplasticity are based on the capability of neurons to adapt to alterations in the internal and/or external environment by modifying specific structures and function; they do this by changing their entire cell surfaces, including the synapses, so that the locations of receptors and other molecules imbedded in the plasma membrane are reorganized. Adaptive or experience-dependent plasticity reveals itself in many forms, ranging from changes in gene expression to changes in neurotransmitter release and in behavior. Even under normal or undisturbed conditions, contacts between neurons are continuously replaced and renewed in the adult and differentiated brain. Enhanced axonal outgrowth and collateral sprouting on the presynaptic site may lead to the formation of new synapses, and existing contacts between neurons may be eliminated by terminal retrograde degeneration. The number of postsynaptic sites on a neuron can be increased or decreased by alterations in the size of its dendritic tree or the spine density on the dendrites.

Remodeling of Brain Cells by Stress

Probably the most thoroughly investigated stress-induced change in neuronal morphology is the regression of apical dendrites of pyramidal neurons, which was first demonstrated in the hippocampus. After this finding, dendritic remodeling of CA3 pyramidal neurons has been repeatedly documented after chronic stress as well as after corticosterone administration.

Similar shortening of dendritic branches, although to a smaller extent, has been observed in granule cells of the dentate gyrus and in pyramidal cells of the hippocampal region CA1, both in chronically stressed and in corticosterone-treated rats. It is assumed that, as a result of the reduced surface area of the neurons, synaptic contacts are also diminished. Indeed, a significant loss of synapses on CA3 pyramidal cells, as well as profound changes in the morphology of the afferent mossy fibers that terminate on these neurons, was detected in chronically stressed or corticosterone-treated animals. Interestingly, even a brief social defeat stress with a long time delay thereafter can significantly reduce the length of apical dendrites but increase the length and complexity of the primary dendrites at the basis of the pyramidal neurons. These data suggest that a brief social conflict is sufficient to drive a dynamic reorganization of neuronal networks with site-selective elimination as well as *de novo* growth of dendritic branches, changes that persist for several weeks after the acute stress exposure.

Contrary to conclusions from initial studies proposing an impact of chronic stress on the number of pyramidal neurons in the hippocampus, recent stereological investigations failed to detect a statistically significant loss of these neurons following prolonged hypercortisolism resulting from stress exposure, corticosteroid administration, or aging. However, it should be noted that the number of hippocampal interneurons or of neurons in the hilus were not specifically examined in these studies. Recently, evidence was provided that long-term psychosocial stress reduces the number of parvalbumin-immunoreactive neurons that are regarded as GABAergic interneurons. This stress effect was observed in the dentate gyrus and in hippocampal region CA3, whereas subfield CA1 was not affected. Thus, the possibility that long-term stress may induce loss of interneurons without affecting the number of principal cells in the hippocampus cannot be ruled out.

Chronic stress alters dendritic morphology not only in the hippocampus but also in the medial prefrontal cortex (mPFC), which modulates various higher cognitive and emotional functions and contributes to regulation of LHPA system activity. Recent reports demonstrated that 3 weeks of either daily restraint stress or daily corticosterone injections led to changes in pyramidal neurons of the mPFC. Up to 20–35% retraction of the distal dendritic branches was seen, together with a significant (16%) decrease in apical dendritic spine density. Interestingly, even repeated vehicle injections resulted in similar, although less pronounced, changes, indicating that with respect to morphology of neurons, the mPFC is even more sensitive to external influences than the hippocampus.

Figure 1 Examples of stress-induced changes in the brain. Hippocampal formation: remodeling of pyramidal neurons characterized by shrinkage of dendrites of pyramidal neurons in region CA3; changes in mRNA and protein reflect that stress regulates expression of genes involved in neuronal differentiation. Prefrontal cortex: remodeling of pyramidal neurons. Amygdala: in the basolateral nucleus, formation of new spines on the dendrites of spiny neurons. Brain stem and pons: activation of monoamine neurons, e.g., those that produce norepinephrine; changes in gene expression.

The amygdala plays a crucial role in regulating fear and anxiety and is essential for the formation of affective memories. Increasing evidence supports a critical role of this brain region in activating the LHPA system. A recent study investigated the impact of chronic stress on the dendritic pattern of amygdaloid neurons. In contrast to findings in the hippocampus, spiny neurons in the basolateral complex of the amygdala exhibited enhanced dendritic branching in response to chronic stress. Examples of stress-induced changes in the brain are summarized in [Figure 1](#).

Stress Suppresses Neurogenesis in the Adult Dentate Gyrus

For a long time, a central hypothesis in neuroscience was that in the mammalian brain, the production of neurons occurs only during development and stops before puberty, and new neurons cannot be formed in the adult brain. This widely held belief has been challenged in recent years by extensive evidence from many mammalian species, including nonhuman primates as well as humans, showing that even in the adult brain, certain areas retain the capability to generate new neurons. Adult spontaneous neurogenesis takes place only in certain regions such as the subgranular zone of the dentate gyrus in the hippocampal formation and the subventricular zone at the lateral ventricle. In the dentate gyrus, newly generated cells

become incorporated into the granule cell layer and attain the morphological and biochemical characteristics of granule neurons. The neuronal nature of these cells is demonstrated by the formation of synapses on the cell bodies and dendrites, extension of axons into the CA3 region, and generation of action potentials.

These observations on neurogenesis were facilitated by the advent of a novel method for detecting cell proliferation and migration. Using the thymidine analog 5-bromo-2'-deoxyuridine (BrdU), which is incorporated into the DNA of dividing cells during the S phase of mitosis, proliferating cells and their progeny can be labeled. BrdU can be visualized by immunocytochemical techniques, and when used in combination with other specific cell markers, it allows determination of the phenotype of the newly generated cells. Using such methods, it has been demonstrated that the majority of newborn cells in the dentate gyrus differentiate into neurons. In other words, it has been shown that the BrdU-labeled cells express the neuronal marker neuron-specific nuclear protein. A smaller proportion of the newborn cells express markers for glial cells such as glial fibrillary acidic protein. Although the new neurons comprise a minuscule proportion of the total neuronal population, their continuous addition over the entire life span implies considerable structural changes within the neural network. The magnitude and ubiquity of adult neurogenesis across vertebrates suggest that it is

functionally significant and not merely a vestige of development.

Stress is a very potent suppressive factor of adult neurogenesis, although a large number of environmental and endogenous parameters also have an impact on the formation of new neurons in the adult brain. The suppression of cell turnover by stress predicts that the age of the cell population, the connectivity of the neurons, and the resulting properties of neuronal circuits in a stressed individual might be substantially different from control situations, with potentially important functional consequences. Several different types of stressful experiences, such as exposure to the odor of a predator, social subordination, or resident–intruder stress, have been shown to inhibit neurogenesis in the dentate gyrus in several species, including nonhuman primates. Furthermore, it appears that the susceptibility of neurogenesis to stress is age dependent in that effects of stress on cell proliferation in the dentate gyrus are more pronounced in old animals than in young ones.

It has become increasingly evident that the antecedents of many illnesses begin in fetal life and, furthermore, that prenatal conditions can have a significant impact on either health or disease in the postpartum period. In a recent study that investigated whether prenatal stress can alter neural, hormonal, and behavioral status in nonhuman primates, pregnant rhesus monkeys were acutely stressed on a daily basis for a quarter of their 24-week gestation using an acoustic startle protocol. At 2 to 3 years of age, hippocampal volume, cytogenesis in the dentate gyrus, and cortisol levels were evaluated in the offspring from stress and control pregnancies. Prenatal stress reduced hippocampal volume and inhibited neurogenesis in the dentate gyrus. These changes were associated with higher cortisol levels in the blood of the monkey offspring, lower levels of exploration, and higher levels of motor behavior. These findings indicate that also in primates, a prenatal environment can alter behavior, may deregulate neuroendocrine systems, and affects the hippocampal structure in a persistent manner.

Plasticity of Astrocytes

The most abundant type of cell within the central nervous system is the glia. In the adult mammalian brain, there are 10 to 50 times more glia cells than neurons. Astrocytes are the most prominent type of glia cells, accounting for about one-third of brain mass. Recent studies have revealed that, in addition to their housekeeping functions, astrocytes are dynamic regulators of synaptogenesis and synaptic strength. These cells control neuronal production, for example, in

the adult dentate gyrus. Thus, abnormalities in glial functioning are likely to contribute to the impairment of structural plasticity in the brain. In line with these ideas, it was recently demonstrated that long-term stress significantly decreased both the number and the volume of astroglial somata. In addition, whether antidepressant treatment with the selective serotonin reuptake inhibitor fluoxetine could afford protection from these stress effects was examined. Indeed, fluoxetine prevented a stress-induced decrease in the number of astrocytes but did not counteract shrinkage of the astroglial somata.

Morphological changes in astrocytes most probably have functional significance with respect to neuron–glia interaction, and because this interaction supports neuronal functioning, interneuronal communication will also be affected by the stress-induced changes. The reduced number or weakened activity of astrocytes could change levels of extracellular glutamate, thus leading to high concentrations of this excitatory neurotransmitter that may have excitotoxic effects. An upregulation of the glial glutamate transporter (GLT-1) in the hippocampus has been reported after chronic stress, and it has been suggested that this might be a compensatory mechanism to control for increased extracellular glutamate concentrations caused by stress. Interestingly, a treatment with the antidepressant tianeptine can block the stress-induced upregulation of GLT-1, and tianeptine also reverses stress-induced dendritic remodeling in CA3. Therefore, the modulation of glial GLT-1 expression in hippocampal region CA3 can be considered a regional neurochemical correlate of dendritic remodeling. These changes in the structure and molecular plasticity of astroglia in response to stress and antidepressant treatment support the notion that glial changes may contribute to the pathophysiology of stress-related disorders such as major depression as well as to the cellular actions of antidepressants.

Plastic Changes of Brain Cells Are Reflected by Alterations in Gene Expression

The stress-induced changes in neuronal structure imply that brain cells adjust their biosynthetic pathways to the new requirements. For example, concomitant with retraction of dendrites, there is probably a reduced need for membrane proteins. Related adaptational processes take place partly on the level of gene transcription. Because various methods, namely, cDNA microarrays, serial analysis of gene expression, and subtractive hybridization, are currently used to

identify genes that are differentially regulated by stress, such genes still appear rather heterogeneous. However, it is already clear that some observations from gene transcription studies are consistent with what has been found with other methods.

In hippocampal formation, expression of several genes known to be involved in neuronal differentiation was found to be downregulated by chronic social stress. Such genes included those encoding the membrane glycoprotein M6a, the CDC-like kinase 1, and a gene encoding a distinct subunit of certain G-proteins, GNAQ. All these genes are known to be involved in neurite outgrowth and neuronal differentiation, thus supporting the view that alterations in neuronal morphology and/or formation of neurons are primary effects of stress, at least in hippocampal formation. Furthermore, expression of neural cell adhesion molecule (NCAM) was found to be downregulated after chronic restraint stress in the hippocampus. NCAM is known to regulate neurite outgrowth and target recognition in the developing nervous system by mediating cell adhesion and regulating signal transduction.

Neuronal plasticity is accompanied by dynamic changes in elements of the cytoskeleton. Alpha-tubulin, which is the major component of microtubules, can be posttranslationally modified, and tyrosinated and acetylated alpha-tubulin are considered markers of dynamically changing and stable forms of microtubules, respectively. Restraint stress for 4 days decreased the expression of tyrosinated alpha-tubulin and increased expression of the acetylated form in the hippocampus. This is in line with the view that stress alters the morphology of pyramidal neurons.

Plastic changes are not restricted to forebrain areas. In a brain stem region, the rat dorsal raphe nucleus, which contains a large number of serotonergic neurons innervating the forebrain, long-term social stress increased the expression of genes involved in regulation of neurotransmitter release (synaptosomal-associated protein 25 and synaptic vesicle glycoprotein 2b). These data support the view that stress increases activity of neurons in the dorsal raphe nucleus.

Data from mRNA or protein expression studies sometimes appear contradictory. However, when interpreting such data, in which brain region, on which cellular level (neurons versus glia), and in which cellular compartment (neuronal cell body versus area of the dendrites versus axon terminal areas) the stress-induced changes were detected should be considered. Finally, besides the sex and the age of the investigated species, both the type and the duration of the stressor play a crucial role with respect to effects of stress on gene expression.

Structural Changes Are Reversible

As shown in animal studies, apical dendrites of hippocampal pyramidal neurons that were shortened by restraint stress or glucocorticoid exposure regained their normal length within 3 weeks after treatment. Several *in vivo* magnetic resonance imaging studies in humans suggest a correlation between hippocampal volume reduction and cumulative glucocorticoid exposure, although exceptions have also been reported. In Cushing's patients who suffer from hypercortisolism, smaller hippocampal volumes returned to normal after successful surgery that led to normal glucocorticoid levels. Thus, up to a certain point, structural changes may be at least partially reversible and may permit restoration of normal functioning. However, it appears that the appropriate intervention should take place within a certain time before the changes become irreversible.

The mechanisms that are responsible for hippocampal volume loss have not yet been identified. Massive neuronal loss following exposure to repeated episodes of hypercortisolemia can be excluded, as no major cell loss was apparent in experimental animals as well as in human postmortem brain tissue. Neurogenesis has been regarded as another mechanism that might affect the volume of the hippocampus. However, hippocampal neurogenesis adds relatively few neurons per day, and those only to the granule cell layer of the dentate gyrus, where an equivalent number of neurons also die. Alternately, hippocampal volume loss might be due to alterations in amounts of the dendritic, axonal, and synaptic components or to changes in levels of glia. Furthermore, stress may induce a shift in fluid balance between the ventricles and brain tissue. This assumption is supported by numerous clinical studies reporting lower volumes of different brain structures in conjunction with enlarged ventricles in patients with affective disorders. However, it remains to be determined whether changes in fluid content cause the aforementioned neuroplastic changes in the neuronal network or just accompany them.

Conclusions

The diverse forms of stress-induced changes in neural cells are of particular interest. They show that even the adult and differentiated brain is a plastic organ. This lifelong plasticity is a prerequisite for the brain to adapt to environmental changes. Plasticity of the neuronal networks is the basis for learning and memory. On the other hand, extensive neuroplastic changes induced by stress may also lead to imbalances in central nervous neural networks. A promising aspect with regard to therapy is that many of these

processes appear to be reversible. Reversibility of structural as well as functional plasticity has already been demonstrated, for example, in response to pharmacological treatments. Thus, progress in our understanding of neural plasticity has profound implications for the treatment of a number of neurodegenerative and psychiatric disorders.

Renal Actions of Dopamine

Adrenocortical Actions of Dopamine

Conclusions

Glossary

*Aromatic
L-amino acid
decarboxylase
(L-AAAD)
(EC 4.1.1.28)*

Previously known as hydroxytryptophan decarboxylase or dopa decarboxylase, L-AAAD catalyzes the decarboxylation of L-5-hydroxytryptophan and L-dopa (L-3,4-dihydroxyphenylalanine) to 5-hydroxytryptamine and dopamine, respectively. It requires pyridoxal phosphate as coenzyme and occurs most abundantly in the kidney, liver, gastrointestinal tract, adrenal gland, and brain.

*Dopamine
(3,4-
dihydroxy-
phenylethyl-
amine)*

A biogenic amine, first identified as an important neurotransmitter in the central nervous system and later discovered to exert actions in peripheral tissues, particularly the cardiovascular system, the renal system, and the adrenal gland.

*Dopamine
receptors*

Plasma membrane proteins that mediate the biological effects of dopamine through the activation of an intracellular second messenger system. Many different classes of dopamine receptors have been defined according to their pharmacological properties using selective agonists and antagonists and/or their molecular structure determined by molecular cloning techniques. Dopamine receptors in peripheral tissues are still distinguished from those in the central nervous system. Although they appear to be similar, they may not be identical, thus D₁ and D₂ denote dopamine type 1 and type 2 receptors, respectively, in the central nervous system, whereas DA₁ and DA₂ denote what are considered to be the equivalent (and perhaps related) receptors in peripheral tissues.

Natriuresis

The loss of sodium ions from circulating plasma into the urine through the action of endogenous chemicals or drugs on the

sodium transport process occurring in the proximal and distal segments of the renal tubules.

*Zona
glomerulosa*

A narrow layer of cells in the outer region of the adrenal gland, situated directly beneath the adrenal capsule, whose specific function is to secrete the steroid hormone aldosterone, which acts on mineralocorticoid receptors in the distal convoluted tubule of the kidney to cause sodium retention and potassium loss.

Renal Actions of Dopamine

Much of our current understanding of the renal actions of dopamine derives from the pioneering work of Leon Goldberg from 1964 onward, which stimulated subsequent research throughout the world.

Effects of Dopamine on the Renal Vasculature

Infusion of dopamine *in vivo* in several animal models leads to vasodilatation and to an increase in renal blood flow with a less marked rise in the glomerular filtration rate (GFR). The limited studies conducted in humans have confirmed these effects, and it appears that the major effect of dopamine is to increase selectively blood flow through the renal cortex rather than through the renal medulla, indicating that dopamine causes a redistribution of renal blood flow, which may reflect the relative distribution of dopamine receptors in the renal cortex versus the renal medulla vasculature. Dopamine receptors that mediate dopamine-induced renal arterial dilatation have been partially characterized using pharmacological agents. In the *ex vivo*-perfused rat kidney, the DA₂ receptor agonist bromocriptine causes vasodilatation, and this response is inhibited by metoclopramide, a DA receptor antagonist. In contrast, in renal microvessels from rabbits, the dopamine-induced relaxation of afferent and efferent glomerular arterioles could be mimicked by fenoldopam and SKF 87516, two specific DA₁ receptor antagonists. In humans, the infusion of fenoldopam causes renal vasodilatation, and in human renal artery segments, dopamine-induced relaxation can be blocked by (+)-sulpiride and SCH 23390, two DA₁ receptor antagonists. It therefore appears that both DA₁ and DA₂ receptors play a role in dopamine-induced vasodilatation and that their respective contribution may be species specific.

Effects of Dopamine on the Renal Tubule

In pharmacological doses, dopamine is a potent natriuretic agent in the kidney. The mechanisms for this natriuretic action appear to be multiple, involving increases in renal plasma flow and GFR, a redistribution of blood flow, and inhibition of the tubular transport of sodium. Dopamine infusion also increases urine cyclic AMP excretion in humans and this effect parallels the increased excretion of sodium into the renal tubules. There is now clear evidence for the involvement of DA₁ receptors in the natriuretic response to dopamine. Infusions of the DA₁ receptor antagonist SCH 23390 via the renal artery in the conscious uninephrectomized dog decrease urine flow rate and sodium excretion, and this effect is inhibited by the DA₁ receptor agonist fenoldopam. These *in vivo* studies have been supported by *in vitro* experiments, which have demonstrated specific binding sites for the DA₁ antagonist SCH 23390 in the proximal tubule of several species, and dose-dependent inhibition of the enzyme Na⁺K⁺-ATPase in the thick ascending limb of the loop of Henle by the DA₁ receptor agonist fenoldopam, which can be blocked by the DA₁ receptor antagonist SCH 23390. The role of DA₂ receptors in the natriuretic action of dopamine still requires further clarification, although these receptors have been identified clearly in the rat proximal tubule.

Effects of Dopamine on Renin Release

The effects of dopamine on renin release are variable, depending on the species and the experimental model. Intrarenal infusion of dopamine in the conscious dog causes a dose-dependent increase in renin release, which is attenuated by the DA₂ receptor antagonist sulpiride. Similarly, in both the isolated perfused rat kidney and dispersed rat renal cortical cell preparations, dopamine stimulates renin release via the activation of DA₂ receptors. In humans, the intravenous infusion of dopamine has been shown either to have no effect on plasma renin activity (PRA) or to increase PRA. In contrast, oral administration of the DA₂ receptor agonist bromocriptine, in humans, causes a decrease in PRA. It has been hypothesized that the stimulatory effects of dopamine on renin release may relate to a direct postsynaptic effect on the renal juxtaglomerular cells and that the inhibitory actions of dopamine on renin release may be presynaptic. Further studies are essential to clarify the actions of dopamine on renin release, especially in humans.

Intrarenal Sources of Dopamine

Renal plasma concentrations of dopamine are low compared to the concentrations of dopamine

required to cause the effects described earlier. It is also apparent that the concentration of dopamine found in urine is vastly greater than what could be accounted for by filtered plasma dopamine. This led to the hypothesis that there were renal sources of dopamine. One hypothesis suggested that dopamine in the kidney was largely derived from the dopamine conjugates sulfate and glucuronide, which are formed in the adrenal medulla and deconjugated in the kidney by the renal enzymes arylsulfatase and β-D-glucuronidase, respectively, releasing free dopamine. Although dopamine conjugates may be one source of renal dopamine, they do not appear to be the major source, as sodium chloride loading in adrenalectomized rats still leads to a marked increase in urine dopamine. A second hypothesis suggested that dopaminergic nerves, which were shown by immunofluorescence studies to be located primarily at the glomerular vascular pole, could release dopamine for local actions on renal hemodynamics in the kidney. In support of this hypothesis, it was demonstrated that renal nerve stimulation in the rat kidney produced vasodilatation that could be inhibited by the DA₂ receptor antagonist sulpiride. It seems likely that dopaminergic nerves could play a role in the regulation of glomerular tuft blood flow and in the regulation of renin release from the juxtaglomerular cells in the afferent arteriole. It is less likely that this source of dopamine plays a role in the natriuretic action of dopamine in the renal tubules. The major source of renal dopamine, which is of specific relevance to the natriuretic effects of dopamine, is undoubtedly that produced by the action of the enzyme aromatic L-amino acid decarboxylase (L-AAAD) on circulating L-dopa. This enzyme is located in the renal tubules, with higher levels in the proximal as compared to the distal segments. An increase in sodium chloride intake causes an increase in renal dopamine and urine dopamine, which may reflect an increase in the uptake of L-dopa from plasma into the proximal tubule (which is a sodium-dependent process), an increase in L-AAAD activity, or both. When the specific inhibitor of L-AAAD, carbidopa, is administered to humans, urine sodium excretion falls as a consequence of the decrease in renal dopamine synthesis.

Pathophysiology of Renal Dopamine

Because the renal actions of dopamine (increased GFR, vasodilatation, and natriuresis) are beneficial for the maintenance of normal renal function, its possible role in several different pathophysiological states, where renal function may be compromised, has been investigated. In some patients with essential hypertension, urinary dopamine excretion is reduced, and an increased sodium intake produces a

paradoxical fall in urinary dopamine in comparison to normal subjects, where sodium loading leads to an increase in urinary dopamine. This led to the hypothesis that the increased retention of sodium in some forms of human hypertension may relate to a defect in the kidney to produce dopamine in order to excrete the excess sodium from the body. Similarly, patients with chronic renal failure show reduced dopamine excretion compared to normal subjects and an impaired renal vascular response to dopamine infusions, which may relate to a loss of dopamine receptors within the kidney.

Adrenocortical Actions of Dopamine

Dopamine acts as a tonic inhibitor of adrenocortical function, and its effects appear to be restricted to the cells in the zona glomerulosa, where it acts specifically to inhibit the secretion of the principal mineralocorticoid, aldosterone.

In Vivo Studies

In 1975, it was observed that the DA₂ receptor agonist bromocriptine inhibited the plasma aldosterone response to furosemide (a diuretic) in humans. This was the first evidence to indicate a role for dopamine as an inhibitor of aldosterone secretion *in vivo*. Further studies in humans then demonstrated that administration of metoclopramide, a nonselective DA receptor antagonist, led to an increase in plasma aldosterone concentration, which was independent of changes in PRA and circulating sodium, potassium, and ACTH concentrations. The stimulatory effect of metoclopramide on aldosterone secretion in humans can be inhibited by the orally active DA agonist ibopamine, which by itself acts as an inhibitor of aldosterone secretion. In addition, experimental evidence suggested that alterations in angiotensin-induced aldosterone responsiveness to changes in dietary sodium chloride may be related to dopaminergic modulation. Although these studies indicate that dopamine can act as a tonic inhibitor of aldosterone secretion, it is not clear whether these effects are mediated primarily by the central nervous system (because the DA agonists and antagonists used can cross the blood-brain barrier) or whether they may relate to more direct actions on the cells in the adrenal zona glomerulosa.

In Vitro Studies

A direct inhibitory action of dopamine on angiotensin II-induced aldosterone secretion was first reported in 1979 by McKenna, who used isolated bovine zona glomerulosa cells. Pharmacological experiments using rat adrenal zona glomerulosa homogenates

later gave evidence for the presence of DA₁ receptors, which were coupled to activation of the G_s-protein, leading to the stimulation of cyclic AMP, and DA₂ receptors, which appeared to couple to the G_i-protein, causing a decrease in cyclic AMP. Compelling evidence suggests that the inhibitory effect of dopamine on aldosterone secretion is mediated by DA₂ receptors, which, when activated, inhibit intracellular Ca²⁺ concentrations or reduce transmembrane Ca²⁺ fluxes within zona glomerulosa cells. In particular, dopamine reduces angiotensin II-stimulated Ca²⁺ influx and angiotensin II-induced inositol phosphate production in rat zona glomerulosa cells. In addition, dopamine inhibits voltage-dependent T-type channels in cultured rat zona glomerulosa cells. No molecular studies have been reported yet on DA₂ receptors in the adrenal cortex, although DA₁ receptors have been shown to be present using *in situ* hybridization techniques to localize DA₁ receptor mRNA and immunohistochemistry to localize DA₁ receptor protein. The function of DA₁ receptors in the adrenal cortex requires further clarification, although tissue culture experiments in the rat zona glomerulosa suggest that activation of this receptor could lead to a stimulatory effect on aldosterone secretion.

Adrenocortical Sources of Dopamine

The concentrations of dopamine that are required to inhibit aldosterone secretion are far in excess of the concentrations of dopamine that circulate in plasma. Although dopamine is synthesized in the adrenal medulla, there is still no clear evidence that dopamine secreted by the adrenal medulla can affect steroid secretion in the zona glomerulosa directly. However, the enzyme L-AAAD, which catalyzes the conversion of circulating L-dopa to dopamine, has been located in the adrenal zona glomerulosa, and there is good evidence to suggest that circulating L-dopa may be the source of adrenocortical dopamine. The effects of dopamine within the adrenal cortex may therefore relate to a paracrine control mechanism, which is mediated by the activity of L-AAAD and the activation of specific DA receptors within the adrenal zona glomerulosa.

Conclusions

The principal actions of dopamine in the kidney are to increase renal blood flow and to promote natriuresis. The natriuretic effects of dopamine may be reinforced by its inhibitory action on aldosterone secretion in the zona glomerulosa cells of the adrenal cortex. These effects of dopamine are, to a great extent, mediated by the enzyme L-AAAD, which is located in the renal cortex and in the adrenal cortex.

The factors that control the expression and function of L-AAAD within the kidney and adrenal cortex, and the further development of selective DA₁ and DA₂ receptor agonists and antagonists, will be of paramount importance to our future understanding of the dopaminergic control of renal and adrenocortical function.

Luteal phase deficiency

Abnormalities of the luteal phase of the menstrual cycle that may include reduced sex hormone concentrations and changes in phase length.

Stereotypy

A locomotor (e.g., pacing) or self-directed (e.g., biting) behavior that is performed precisely the same way, repeatedly in quick succession.

Social Stress and the Likelihood of Conception
Social Stress and Pregnancy Outcome
Long-Term Health of the Offspring

Glossary

<i>Functional hypothalamic chronic anovulation</i>	Inhibition of ovulation due to stress.
<i>Hypothalamic-pituitary-adrenocortical axis</i>	A major stress reactive system in the body involving the hypothalamus, pituitary, and adrenal glands.
<i>Hypothalamic-pituitary-gonadal axis</i>	The pathway of the reproductive system that controls gonadal function.

Reproductive failure rates are uniformly high across the mammalian order. From the perspective of human medicine, reproductive failure is often viewed as evidence of a disorder that requires treatment. However, mammologists and evolutionary biologists understand reproductive failure as an evolutionary safeguard against wasting energy on reproduction when the likelihood of a successful outcome is relatively low. From this perspective, it makes sense that the reproductive system would be especially sensitive to environmental variables that might influence the outcome of reproductive effort. Female mammals have a greater investment in reproduction than males, and the female reproductive system is particularly sensitive to environmental factors signaling adverse conditions for successful reproduction. Thus, there is less data available

concerning stress effects on reproductive function of males than on that of females. For species that live in groups, social factors are key aspects of the environment. One type of social environmental influence to which the reproductive system of mammals appears quite sensitive is social stress. Social stress is defined here as a social environmental factor that perturbs homeostasis and elicits behavioral or physiological change. The purpose of this article is to examine the evidence of parental social stress on reproductive health, including fertility, pregnancy outcome, neonatal health, and the lifelong health of the offspring.

Social Stress and the Likelihood of Conception

Physiological Mechanisms

The mechanisms by which social stress may influence the likelihood of conception are not completely understood. However, stress-induced activation of the hypothalamic-pituitary-adrenocortical (HPA) axis inhibits the hypothalamic-pituitary-gonadal (HPG) axis at multiple levels. Corticotropin-releasing hormone (CRH) inhibits hypothalamic gonadotropin-releasing hormone (GnRH). CRH stimulates pituitary adrenocorticotropin (ACTH) secretion, which in turn increases adrenal glucocorticoid secretion. Glucocorticoids inhibit GnRH secretion, as well as pituitary luteinizing hormone and ovarian estrogen and progesterone secretion. CRH also stimulates β -endorphin, which in turn inhibits GnRH secretion. Gonadal dysfunction results from alterations in GnRH pulsatility from the hypothalamic pulse generator impairing ovulation. Other neurotransmitters that mediate stress effects on the GnRH pulse generator include dopamine, neuropeptide Y, norepinephrine, γ -aminobutyric acid (GABA), and endogenous opioid peptides.

Dopamine receptors appear to mediate stress-induced transcription of hypothalamic CRH and proopiomelanocortin, from which a number of peptides are derived, including ACTH and endogenous opioids. The results of a series of nonhuman primate studies suggest that dopamine is involved in the effect of one type of social stress on the reproductive system. A major social organizing mechanism of primate society is the social status hierarchy. Among group-living primates, low social status, or social subordination, appears stressful and is associated with lower reproductive output in females. Socially subordinate female cynomolgus monkeys (*Macaca fascicularis*) receive more aggression, maintain a high level of vigilance, are groomed less by conspecifics, and spend more time alone than their dominant counterparts. Their adrenal glands hypersecrete cortisol, and

they are insensitive to glucocorticoid negative feedback. The central dopaminergic function of these females is also deranged, as evidenced by insensitivity to haloperidol, lower cerebrospinal fluid levels of homovanillic acid (HVA), a dopamine metabolite, and lower D₂ receptor binding potential in striatum observed by positron emission tomography. In males, the relationship between social subordination stress and reproductive output is less consistent than in females. Associations between social status and offspring sired are observed in some years but not others. Likewise, the relationship between low social status and activated HPA function is less apparent in male than in female Old World primates. However, central dopaminergic function of subordinate males is different than that of dominants, as evidenced by lower cerebral spinal fluid (CSF) HVA concentrations and lower striatal D₂ receptor binding potential. Thus, social subordination stress may alter central dopaminergic function, increase HPA activity, and inhibit HPG function.

Another mechanism that may mediate stress effects on conception involves reactive oxygen species (ROS). ROS can modify cell function and endanger cell survival. Because these are normal consequences of oxygen metabolism, ROS must be continuously deactivated by antioxidant defense mechanisms to avoid oxidative stress. There is some evidence that psychosocial stress may increase ROS, decrease DNA repair, and alter rates of apoptosis. Thus, oxidative damage may occur during stress. High levels of ROS are found in the semen of infertile men and the peritoneal and follicular fluid of infertile women.

Inhibition/Delay of Sexual Maturation

Two hypotheses address the relationship between social stress and sexual maturation. The social suppression hypothesis posits that stress suppresses sexual development. In support of this hypothesis, it has been widely observed in monkeys that low social status is associated with delayed sexual maturation and that dominant females reproduce at an earlier age than subordinate females. Likewise, girls from higher social classes enter puberty earlier than girls from lower social classes. Delayed sexual maturation following severe stress (e.g., war) has been documented in boys and girls, though is not well studied. In contrast, the psychosocial acceleration theory posits that under certain types of stressful conditions in which low-quality parental investment signals that parental investment does not promote reproductive success, sexual maturation may accelerate so that reproduction may occur earlier and more often. There is some evidence that family warmth and positivity may

delay, and family conflict and coercion may accelerate, pubertal development. Thus, the nature of the psychosocial stressor may be critical in predicting effects on sexual development.

Inhibition/Delay of Ovulation

Low social status is associated with inhibition of ovulation in baboons and macaques (*Macaca* spp.). Female cynomolgus monkeys (*M. fascicularis*) have menstrual cycles that are very similar to those of women. Socially subordinate female cynomolgus monkeys have low luteal phase progesterone concentrations, low follicular phase estradiol concentrations, a greater proportion of menstrual cycles with impaired luteal function, and a greater proportion of anovulatory menstrual cycles. Furthermore, when female monkeys change social status, their menstrual cycle characteristics change also (Table 1), suggesting that the reproductive system of these females is exquisitely sensitive to their social environment.

Socially suppressed ovarian function in these monkeys is associated with deleterious effects on the skeletal and cardiovascular systems, suggesting that socially induced hormonal impairments unaccompanied by amenorrhea have far-reaching effects on health.

Social stress may also inhibit ovulation in women, a condition referred to as functional hypothalamic amenorrhea or functional hypothalamic chronic anovulation (FHCA). Diagnosis is by exclusion of all other potential organic causes. The best indicator that FHCA is stress related is that it is generally accompanied by hypercortisolemia. Note that socially subordinate female monkeys that are stressed do not necessarily have more anovulatory cycles than their nonstressed dominant counterparts. Thus, in extrapolating to women, it is important to consider that stress-induced suppression of reproductive function may not manifest as frank amenorrhea, complicating diagnosis. In women, perturbations in GnRH pulsatility may result in ovarian dysfunction manifested

as amenorrhea, polymenorrhea, oligomenorrhea, or luteal phase deficiency, the latter of which may go undetected unless infertility issues arise. FHCA also appears reversible in women. The prevalence of FHCA varies depending on the subpopulation considered. Estimates in the general population range from 2 to 7%, whereas in high-risk populations, such as women going to college or joining the armed forces and women with depression, the prevalence may be as high as 70%. Under these circumstances ovulatory impairment appears to coincide with psychosocial stress and precede nutritional stress. Women that develop FHCA are more likely to be anxious, be perfectionists, and have difficulty coping.

Impairment of Hypothalamic-Pituitary-Testicular Function

During periods of social instability, low social status and aggression received are both associated with suppressed plasma testosterone concentrations in male macaques and baboons. In men, stressful events (e.g., work stress, exams, or competitions) may decrease testosterone levels, which can lead to decreased libido, diminished muscle mass, change in hair growth, and decreased spermatogenesis. Decreased testosterone may be due to perturbations in GnRH pulsatility or to direct effects of cortisol on testicular Leydig cell testosterone production. Social stress (e.g., death of a close family member) can result in oligoasthenozoospermia, which may remain undetected unless infertility issues arise. Decreased sperm number and quality are associated with decreased fertility.

Social Stress and Pregnancy Outcome

Physiological Mechanisms

There are several ways in which neuroendocrine stress responsivity may affect pregnancy. CRH regulates the HPA responses to stress. During pregnancy

Table 1 Effect of changing social status on menstrual cycles^a

Initial status	Subordinate		Dominant		Final status effect $p \leq$
Final status	Subordinate	Dominant	Subordinate	Dominant	
Number of cycles	15.2 (0.94)	15.4 (1.03)	14.4 (1.52)	15.1 (1.1)	0.60
Percent ovulatory	68.1 (9.19)	91.4 (3.36)	81.6 (6.34)	88.4 (4.42)	0.03
Percent impaired	19.4 (5.21)	4.2 (1.65)	8.4 (2.8)	8.1 (2.60)	0.08
Percent anovulatory	12.5 (6.00)	4.5 (2.21)	9.9 (5.44)	3.5 (2.76)	0.17
Progesterone (ng/ml)	6.7 (0.96)	10.4 (1.72)	8.1 (0.98)	9.6 (0.97)	0.03

^aMeans and standard errors. Social status of 42 female cynomolgus monkeys living in small social groups was documented for 2 months. The constituency of the social groups was changed such that half of the subordinates became dominant and half of the dominants became subordinate, and social status and menstrual cycle characteristics were documented for 24 months.

it also coordinates and controls the physiology of parturition. CRH is produced in the placenta, and placental CRH is stress sensitive. Maternal pituitary-adrenal hormones stimulate placental CRH secretion. Maternal stress is positively associated with circulating ACTH concentrations, and maternal social support is negatively associated with circulating concentrations of ACTH, β -endorphin, and cortisol. Maternal β -endorphin secretion during the third trimester is associated with increased fetal heart rate reactivity and decreased uroplacental blood flow, the latter being consistent with fetal hypoxia. Elevated CRH levels are associated with preterm labor and preterm delivery. Onset of the birthing process also involves oxytocin, vasopressin, and prostaglandins, as well as HPA activation. Secretion of these hormones may be altered by stress, thus affecting the timing of birth. Indeed, uteri from preterm deliveries appear to be hypersensitive to oxytocin. Stress-induced catecholamine and oxytocin may reduce the threshold of uterine contractility, thus resulting in preterm labor.

There is substantial evidence that HPA axis peptides (including ACTH and β -endorphin) affect the development of fetal brain and behavior and that perinatal exposure to ACTH and its analogues permanently alters growth and behavior. Thus, maternal stress may alter the trajectory of development beginning *in utero*.

Neuroendocrine stress responses are known to suppress the immune system; however, these processes have been little studied during pregnancy. Pregnancy involves immunosuppression in order to avoid fetal rejection. Thus, stress-related immunosuppression may be superimposed on the normal physiological immunosuppression of pregnancy, potentially affecting pregnancy outcome. Stress-induced immunosuppression increases vulnerability to infection. Infection, in turn, may induce preterm delivery. Preeclampsia is also associated with altered immune function and thus may be affected by stress-induced immunosuppression. Preterm birth is associated with enhanced expression of pro-inflammatory cytokines. Pro-inflammatory cytokines stimulate prostaglandin and metalloprotease synthesis in gestational tissues, which promote spontaneous labor and rupture of membranes. They also stimulate fetal-placental production of steroids and CRH, which promote parturition.

Norepinephrine and epinephrine are stress-responsive catecholamines that decrease blood flow to the uterus. Decreased uterine blood flow may cause hypoxia, hypotension, bradycardia, and malformations in the fetus. Hypoxia may result in increased ROS production. Oxidative stress due to increased ROS and/or decreased antioxidant defense mechanisms has been implicated in miscarriage and preeclampsia.

Thus, maternal, placental, and fetal neuroendocrine, immune, and cardiovascular processes link maternal stress during pregnancy with adverse pregnancy outcomes.

Failure of Implantation

It is difficult to determine failure of implantation, especially to discriminate it from ovulatory difficulties. Both social status and current ecological conditions affect the likelihood of successful implantation in yellow baboons. Under poor environmental conditions, socially dominant females (with low social stress) are more likely to achieve successful implantation than their subordinate, stressed counterparts. Likewise, in an *in vitro* fertilization study, implantation rates were reportedly higher in women with relatively low cardiovascular reactivity to a standardized laboratory stressor.

Spontaneous Abortion

There is an association between spontaneous abortion and psychological stress in pigtail macaques (*M. nemestrina*). Low social status, psychological stress, low control, and low social support have been associated with spontaneous abortion in humans. In 192 women with recent spontaneous abortions, it was found that recent negative life events significantly increased the likelihood of spontaneous abortion of chromosomally normal conceptions. In perhaps one of the largest studies available ($n = 214,108$), adverse pregnancy outcomes, including spontaneous abortion, were most frequent in women working in jobs characterized by high demand and low control. In another study of several thousand women, stressful work increased spontaneous abortion by a factor of 2.45 (95% confidence interval [CI] 1.03–5.81) in older women, 2.96 (95% CI 1.16–7.52) in smokers, and 2.27 (95% CI 0.97–5.27) in primigravid women. Thus, stressful life events, work characterized by high demand and low control, and stressful work may increase rates of spontaneous abortion.

Maternal Stress and Neonatal Mortality

Associations of neonatal mortality and maternal social stress are well documented in nonhuman primates. Rhesus macaque infants born to socially dominant females have a higher rate of survival than those born to socially subordinate mothers. Higher mortality also has been observed among offspring of psychologically stressed pigtail macaques. Chimpanzee and gorilla offspring born to subordinate mothers are subject to greater neonatal mortality than those born to dominants, in part due to infanticide. Maternal psychological stress and low social status have

been associated with neonatal mortality in humans. In a large study ($n = 214,108$), adverse pregnancy outcomes, including stillbirth, were most frequent in women working in jobs characterized by high demand and low control. Maternal risk factors for sudden infant death syndrome (SIDS) include low socioeconomic status (SES), unmarried status, teen age, less education, depression, drug use, and ethnicity. These characteristics are also risk factors for low birth weight, and low birth weight is a powerful predictor of SIDS. While it is difficult at this time to tease apart the relative contributions of these risk factors, all may involve increased maternal stress during gestation.

Maternal Stress and Neonatal Morbidity

The effects of maternal social stress during pregnancy on neonatal morbidity are more subtle and difficult to determine than neonatal mortality. Measures of neonatal morbidity include labor and delivery complications, gestational age, Apgar scores, birth weight, and neuromotor and neurobehavioral development during the first 30 days.

A series of studies in squirrel (*Saimiri boliviensis*) and rhesus monkeys demonstrated that mild maternal stress (e.g., removal from a home cage daily followed by 10 min of white noise during mid-late gestation) results in lower birth weight, impaired neuromotor development (as measured by a modified Brazelton Newborn Behavioral Assessment Scale), and impaired neurobehavioral development of attention and orienting. Early gestation stress was associated with more profound impairments to growth and neuromotor development during the first postnatal month than late gestation stress. These impairments are mimicked by administering ACTH to pregnant females for 2 weeks at mid-pregnancy, suggesting that activation of the HPA axis is instrumental in the deleterious effects of maternal prenatal stress on infant morbidity. Similar decrements in offspring development continue into adolescence (see later).

A large number of studies have been conducted to test the hypothesis that prenatal maternal stress causes infant morbidity in humans, and the balance of the literature supports this hypothesis. Birth weight and gestational age are the most commonly measured outcome variables. Low birth weight can be due to preterm delivery (less than 37 weeks gestation with an appropriate infant weight for gestational age) or to retarded fetal growth (inappropriate weight for gestational age). Maternal anxiety and depression result in low birth weight and perhaps smaller head size.

The magnitude of the effect is comparable to that of smoking. Composite measures of maternal prenatal stress (including some combination of trait or state anxiety, depression, life events, social support, and self esteem) best predict preterm delivery/low gestational age. Likewise, the association between psychosocial stressors and birth weight is strongest when composite measures of maternal stress (e.g., exposure to stressors such as life event scales, social support, anxiety, health risk behaviors) were used. The timing of the stress is important. Low birth weight and shorter gestational age have been observed when the stressors occur in the first trimester, whereas preterm delivery is associated with third trimester stress. In one of the largest studies available ($n = 214,108$), adverse pregnancy outcomes, including light-for-date birth weight and full-term low birth weight, were most frequent in women working in jobs characterized by high demand and low control.

Long-Term Health of the Offspring

Maternal Stress and Offspring Central Nervous System (CNS) Function

The effects of maternal stress during gestation have been shown to affect CNS function of rhesus monkeys (*M. mulatta*) through adolescence (4 years of age). Six-month-old offspring from control mothers and mothers that experienced a daily mild stressor (three random white noise bursts over 10 min) were evaluated during the latter half of pregnancy. In a response to a novel environment, offspring of prenatally stressed mothers exhibited more disturbance behavior (e.g., clinging to attachment object, self-directed stereotypic behaviors) and lower levels of gross motor and exploratory behavior than those of nonstressed mothers. At 8 and 18 months, prenatal stress-derived monkeys had higher CSF concentrations of metabolites of dopamine and norepinephrine, suggesting altered CNS function. The behavioral responses of these monkeys to social separation stress were evaluated. Disturbances in exploratory, locomotor, and clinging behavior observed at 6 months of age continued, and disturbances in social play were also observed. The effects of prenatal stress on later behavioral responses to stress were more profound for social than for nonsocial behavior, and suggest that offspring from prenatally stressed mothers are behaviorally hyperresponsive to stress. Between 6 months and 1 year of age, male offspring of prenatally stressed mothers had smaller, and females had larger, corpus callosum. At 14–19

months of age, prenatal stress-derived monkeys had higher ACTH and cortisol levels at baseline and under anesthesia. Furthermore, in response to stress, prenatal stress-derived offspring had higher ACTH and similar cortisol responses as control offspring. These observations suggest that the HPA axis of offspring of primate mothers stressed during pregnancy hyperresponds to stress later in life, and that the components of this stress-responsive system are dysregulated. The behavior of these prenatal stress-derived offspring was characterized again at 4 years of age, a time corresponding to human adolescence. At this age, the behavioral pathology of the prenatal stress-derived offspring was profound and included greater locomotion, stereotypies (pathological repetitive behaviors such as rocking), clinging, and self-clasping. These monkeys explored less in a novel environment and engaged in less social interaction in a playroom environment. At 5–7 years of age, *in vivo* imaging studies revealed a perturbed striatal dopaminergic system, which is critically involved in drug abuse vulnerability and sensitive to adult social stresses. Taken together, these observations suggest that prenatal stress can have profound and long-term effects on the behavior and neurobiology of primate offspring that is particularly apparent in response to stress.

Similar data from human studies are difficult to acquire. However, the results of a number of studies suggest that prenatal stress may perturb CNS function of newborns. There are reports of increased fetal activity associated with maternal anxiety and catastrophic stress due to earthquake. Anxious, type A, or depressed mothers have newborns who cry more and are more difficult to soothe. First trimester maternal stress and anxiety have been associated with low scores on cognitive and psychomotor tests, poor adaptation to novel environments, and difficult behavior in infants 8 months of age. At 9 years of age, attention deficits and aggressiveness were more common in the offspring of mothers who were anxious during pregnancy. Maternal stress is also linked to offspring psychopathology. Schizophrenia, in particular, has been linked to prenatal stress. Maternal exposure to death of a loved one, influenza infection, or catastrophic stressors increase the risk of the offspring developing schizophrenia, the onset of which is most common between 16 and 30 years of age.

The Significance of Low Birth Weight to Health in Later Life

Cardiovascular disease (CVD) is the leading killer of men and women. Low birth weight has been

associated with all-cause mortality, coronary heart disease, stroke, type II (non-insulin-dependent) diabetes mellitus, hypertension, and the metabolic syndrome. The metabolic syndrome is a cluster of characteristics (e.g., abdominal fat deposition, hyperglycemia, hyperinsulinemia, hypertension, and an atherogenic lipid profile) that greatly increase risk of CVD. Given the patterning of associations, it appears that low birth weight may be associated with lifelong derangement of the metabolic function of several major systems that culminates in increased risk of cardiovascular disease. Hypotheses currently being tested to explain fetal programming of adult health include the possibility that suboptimal environmental influences on fetal growth lead to permanent changes in organogenesis (i.e., particularly those involved with energy metabolism) that may serve to preserve the growth of certain organs, like the brain, to the expense of the function of other systems. Prenatal exposure to excess cortisol is considered a likely mechanism by which maternal stress during gestation may lead to fetal programming of cardiovascular, metabolic, and neuroendocrine disorders in adult life.

Exaggerated maternal stress responses can bathe the fetus in excessive glucocorticoids, resulting in an adult programmed for exaggerated HPA responses to stress. If this adult gestates young, she may also produce offspring with exaggerated stress responses, and thus intergenerational transmission of stress reactivity and subsequent ill health may be perpetuated. Indeed, low-birth-weight women are more likely to have low-birth-weight babies.

Summary

Glossary

Hypothalamic-pituitary-adrenal axis

The complex of (1) specialized cells in the hypothalamus that secrete the neuro-endocrine peptide, corticotropin-releasing hormone, (2) cells in the anterior pituitary that secrete adrenocorticotropin (ACTH), and (3) the adrenal gland that secretes glucocorticoid and mineralocorticoid hormones in response to ACTH.

Endogenous opioid peptides

Peptides released both within the brain and from pituitary cells that inhibit binding of morphinelike compounds to receptors.

Individual variability in stress responsiveness

Difference in physiological responses among individuals in a particular species to a given stress.

<i>Reproductive hormones</i>	Pituitary gonadotropins, including luteinizing hormone and follicle-stimulating hormone, and gonadal steroid hormones, including estradiol, progesterone, and testosterone.
<i>Social stress</i>	Stress arising from interactions with others or the perception of other's attitudes.
<i>Social status</i>	Placement of a particular animal within a social hierarchy, with subordinate animals deferring to the wishes of more dominant animals.

Both acute and chronic psychological and social stresses can impair reproductive hormone secretion in a variety of nonhuman primate species. This impairment can be subtle, consisting of a mild suppression in reproductive hormone secretion, or can be dramatic, causing a complete suppression of fertility and reproductive behavior. Among individuals there are marked differences in the responsiveness of the reproductive axis to social stresses, with factors contributing to this variability including the type of stress experienced, the magnitude and duration of stress, the perception of the stress by the individual, the social status of the individual, the concurrent level of aggressive behavior displayed by the individual, seasonal cues, and the prior level of activity within the reproductive axis (Figure 1). Mechanisms contributing to social stress induction of reproductive dysfunction include activation of the adrenal axis, increased secretion of endogenous opioids, increased prolactin release, and changes in sensitivity to gonadal steroid hormone feedback; however, in most forms of social stress the pathways leading to reproductive dysfunction remain to be elucidated.

Overview

While many forms of physical stress, such as energy restriction, temperature stress, infection, pain, and injury, have been clearly associated with the impairment of reproductive function, the effects of behaviorally induced stresses, i.e., psychological and social stresses, on the activity of the reproductive axis have been less well studied. The topic of behaviorally mediated stresses on reproductive function is of particular interest in primate species, which live in complex social groups and have higher cortical brain areas similar to humans, making study of these species particularly useful in understanding how such stresses may impact on reproduction and fertility in humans. This article provides a review of what is known currently about the role of psychological and social stresses in modulating the activity of the reproductive axis in nonhuman primate species. The review will show that the impact of psychological and social stresses on reproductive function is associated with significant variability among individuals and will detail the factors known to influence this variability in stress responsiveness.

Stress-Induced Impairment of the Hypothalamic-Pituitary-Testicular Axis in Male Primates

A variety of acute psychological stresses have been shown to cause the acute suppression of circulating luteinizing hormone (LH) and testosterone levels in male nonhuman primates. Examples include studies showing that the restraint of male rhesus monkeys suppresses pulsatile LH and testosterone release, and that mean testosterone concentrations decline rapidly in male rhesus monkeys in response to aggressive attacks by other monkeys. However, in other studies

Figure 1 Schematic diagram of variables important in determining whether psychological stress will stimulate or inhibit reproductive function within an individual.

the acute response to stress in male primates has been shown to be more variable. In baboons, darting and capture have been shown to lead to an immediate suppression of testosterone in some animals, but to an initial increase in plasma testosterone levels followed by a much more subtle decline in other animals. Similarly, in response to pairing with an unfamiliar male animal, some male squirrel monkeys have an acute release of testosterone, whereas other males do not show this initial rise in testosterone. In this case, monkeys showing acute testosterone release are the behaviorally dominant monkeys in the pairs, whereas subordinate monkeys fail to show the acute testosterone release. Although many acute psychological stressors can suppress reproductive hormone secretion in male primates, not all such stresses have this effect. For example, our laboratory has used the acute psychological stress of exposing male rhesus monkeys to the sight of leather capture gloves to examine the physiological sequelae of acute psychological stress and has shown that although heart rate and cortisol release are elevated acutely in this paradigm and that immune cell function is suppressed for a number of hours, LH and testosterone secretion are not influenced. Although this stress evokes physiological stress responses in several systems, it seems likely that monkeys perceive this stress as being less threatening than a stress such as an aggressive attack by other monkeys. Thus, the perception of severity of stress is likely to be important in determining whether the stress will lead to a suppression of reproductive hormone secretion.

A number of chronic social stresses have also been associated with a marked and sustained suppression of reproductive hormone secretion in males, again with several investigations showing a marked dichotomy in response between dominant versus subordinate males, and other investigations showing that variability in the response of the reproductive axis to stress is dependent on environmental factors. Examples of prolonged stresses shown to lead to decreased testosterone secretion include social stress associated with loss or removal of the dominant male in the social group, housing males in all male social groups, and housing males in isolation. Interestingly, several social factors appear to modulate the response of the reproductive axis to stress in such conditions of chronic social stress. In a number of studies, a high degree of correlation between aggressiveness and testosterone titers, with the more aggressive males showing higher circulating levels of testosterone, has been reported. There also appears to be an interaction between the social status and the level of environmental stress, such that in periods of social stability there can be no difference in plasma testosterone levels

between dominant and subordinate animals, but in periods of social instability the dominant animals can show higher plasma testosterone levels than the subordinate males.

Based on the ability of both acute and chronic social stress to suppress reproductive hormone secretion, it has been posited that social status (i.e., dominance rank) plays an important role in determining the lifetime reproductive success in primates, with subordinate animals experiencing a greater degree of social stress and having a lesser degree of reproductive success. However, evidence for this hypothesis is weak, and it would appear that again multiple factors, including current dominance rank, time of year, magnitude of stress, aggressiveness of the animal, and level of activity of the reproductive axis prior to stress exposure, can all play roles in modulating reproductive success, in the same way these factors influence reproductive hormone secretion. Thus there are a number of instances in which subordinate males have similar long-term reproductive success when compared to dominant males.

Stress-Induced Impairment of the Hypothalamic-Pituitary-Ovarian Axis in Female Primates

Chronic social stress can also impair reproductive function in female nonhuman primates, which often show an increase in the length of the menstrual cycle and an increased incidence of anovulation in response to being maintained in stressful situations. In general, stress-induced lengthening of the cycle is characterized predominantly by a lengthened follicular phase and a normal length luteal phase. Social stresses associated with the inhibition of reproductive function include moving females to new social groups, housing in isolation, and even moving singly housed females to a new room where they can only interact with other animals through visual, auditory, and olfactory cues.

A number of studies have shown that dominant females have greater reproductive success than subordinate females in various nonhuman primate species. It has been widely assumed that subordinate females experience more stress than dominant females and that this stress plays a role in the relative suppression of reproductive function. This assumption has been born out by studies showing that subordinate female macaques housed in small group settings have larger adrenals and an enhanced adrenal responsiveness to adrenocorticotropin (ACTH) stimulation accompanying an increased incidence of anovulatory cycles. However, as in males, evidence shows that dominance rank may only determine reproductive success

when environmental resources are limiting, at least in some species. This supports the notion that a number of environmental and social factors play a role in determining the impact of stress exposure on reproductive function.

Social Status as a Determinant of Reproductive Capacity

In the preceding paragraphs, evidence has been presented showing that exposure to stress can suppress reproductive hormone secretion in nonhuman primate species that show normal adult reproductive function in nonstressed conditions. It seems likely that the ability of stress to impair reproductive function in these animals may well be analogous to the ability of psychological stress to impair reproductive function in humans. In addition, however, there are several species of nonhuman primates in which social interactions play a more absolute role in determining the activity of the reproductive axis, and this appears to be particularly true in the case of females. Specifically, in talpoin monkeys (*Miopithecus talapoin*) and marmosets, only the dominant female in a social group is reproductively active and all subordinate females are reproductively inactive until removal of the dominant female from the social group. As discussed later, evidence shows that social stress cues play an important role in this form of regulation of the reproductive axis.

In social groups of common marmosets (*Callithrix jacchus*), only the dominant female is reproductively active and bears offspring. As the female offspring mature in their natal group they remain reproductively quiescent, essentially held in a prepubertal state. These subordinate females display no signs of ovulation, they have low circulating concentrations of LH and ovarian steroid hormones, and the ovaries remain dramatically smaller than those of the dominant female, containing only small follicles and stromal tissue. The infertility can be reversed by several weeks of treatment with a pulsatile gonadotropin releasing hormone (GnRH) regimen, indicating that the suppression of reproductive function is at a central level to block the GnRH drive to the reproductive axis. Similar findings have been reported in female talpoin monkeys.

In these species, subordinate males also appear to have a suppression of reproductive axis activity in comparison to the dominant males, but the impairment of the reproductive axis is not as severe in males as in females. In male marmosets, the subordinate animals living in social group settings have lower circulating concentrations of LH and testosterone. In male talpoin monkeys, there is a general trend for the most dominant males to display the greatest

amount of sexual behavior and the most subordinate males to show little or no sexual behavior when housed in social groups. When housed in social groups of multiple males and females there is also a trend for the dominant males to have higher circulating concentrations of testosterone than the most subordinate males, but on a day-to-day basis this relationship between social rank and plasma testosterone concentrations is not always apparent. Interestingly, when male talpoin monkeys are moved to individual cages the correlation between social rank and plasma testosterone concentrations completely disappears. It thus appears that social rank modulates the activity of the reproductive axis, but that this effect is only apparent when monkeys are in a social setting where dominance hierarchies are in place.

The two most common routes by which social cues can suppress reproductive function in mammals are by behavioral intimidation and by pheromonal cues. Although there is some evidence that pheromonal cues play a role in the reproductive quiescence in the subordinate animals of these species, ablation of the olfactory epithelium and vomeronasal organ does not prevent suppression of reproductive function in subordinate animals, clearly indicating that other cues play a role in maintaining reproductive suppression. Behavioral intimidation of subordinate animals is apparent in both of these species. When marmosets are first placed in social groups there is a brief period where they receive an increased amount of harassment and intimidation from dominant animals, and in talpoin monkeys the place within the social hierarchy of a particular animal is established by the direction and frequency of aggressive interactions between various animals. The most dominant animals receive the least amount of aggression from others in the social group, whereas the most subordinate animals receive the most aggression. In addition, subordinate animals visually monitor more dominant animals at very frequent intervals. Subordinate animals also show an increase in circulating concentrations of the stress hormones, prolactin and cortisol. Cumulatively, data discussed earlier indicate that the stress associated with subordinate status within a social group at least partially underlies the suppression of reproductive function in these species of primates.

Mechanisms Underlying Stress-Induced Reproductive Dysfunction in Primate Species

Activation of the Adrenal Axis

In many cases, social stress-induced reproductive dysfunction is accompanied by an activation of the

hypothalamic-pituitary-adrenal axis, and it is possible that in these cases hormones of the adrenal axis may play a role in suppressing reproductive hormone secretion, and ultimately sexual behavior. Several secretory products of the adrenal axis have been shown to be capable of suppressing activity of the reproductive axis. Corticosteroids have been shown to both directly inhibit GnRH secretion and suppress the pituitary responsiveness to GnRH, although these effects of corticosteroids require high levels sustained over a several-week time course. Corticotropin-releasing hormone (CRH), the central hypothalamic-releasing factor of the adrenal axis, has also been shown to be a potent inhibitor of LH secretion when it is administered in pharmacological experiments. In addition, for some forms of physical stress, the administration of CRH antagonists can prevent the stress-induced suppression of reproductive hormone secretion.

Despite the evidence that elevated activity of the adrenal axis often accompanies suppressed reproductive hormone secretion in various forms of psychological and social stress in primates, there is no evidence to date that in these psychological stress conditions that activation of the adrenal axis is indeed causing the suppression of the reproductive axis. A causal relationship would only be established if it could be shown that blocking activation of the adrenal axis reversed the psychological stress-induced inhibition of the reproductive axis, and such experiments have not been performed to date. In addition, it is important to recognize that in at least several situations where other physical stresses are associated with both an increase in adrenal hormone secretion and a decrease in reproductive hormone secretion that such studies have shown that activation of the adrenal axis is not causing the suppression of the reproductive axis. Thus, the role that activation of the adrenal axis actually plays in causing suppression of the reproductive axis in any conditions of social or psychological stress remains to be elucidated.

Other Mechanisms

Evidence shows that the increased release of endogenous opioid peptides plays at least a partial role in suppressing the activity of the reproductive axis in some forms of social stress. There are several reports that administration of the opioid receptor antagonist, naloxone, can restore or partially restore LH secretion in conditions of psychological stress, including the suppression of LH and testosterone secretion in chair-restrained rhesus monkeys and after anesthetic darting in olive baboons. Naloxone can also restore LH secretion when administered to ovariectomized, subordinate marmosets. However, because opioid receptor antagonists are not effective in restoring activity of the reproductive axis in all forms of social

stress-induced reproductive dysfunction, clearly other mechanisms are also involved in transmitting information about social stress to the reproductive axis.

Subordinate talpoin monkeys show a marked elevation in circulating prolactin levels compared to dominant animals, and it is possible that this increase in prolactin may play a role in suppressing the activity of the reproductive axis in this species, in that bromocryptine, a dopamine agonist, which reduces prolactin secretion, is able to at least partially restore reproductive hormone secretion. However, prolactin does not appear to mediate stress-induced suppression of the reproductive axis in all species. Even in another primate species in which subordinate animals show marked suppression of the reproductive axis, the marmoset, prolactin levels are not elevated and do not appear to play a role in mediating the inhibition of reproductive function.

In marmosets, evidence shows that the social suppression of reproductive function is associated with an increased sensitivity of the reproductive axis to estradiol negative feedback, as shown by the ability of low levels of estradiol to inhibit LH secretion in subordinate, but not dominant, female marmosets. In talpoin monkeys, removal of the subordinate female from the social group leads to a restoration of reproductive hormone secretion and increased sensitivity of the reproductive axis to estradiol-positive feedback. The neural mechanisms that underlie changes in sensitivity to estradiol feedback in these conditions remain unknown.

A review of all the studies examining social stress-induced suppression of the reproductive axis suggests that there are likely to be multiple neural systems that contribute to the inhibition of reproductive function in times of social and psychological stress. Clearly, there appear to be species differences in the neural pathways leading to reproductive inhibition. However, perhaps more interesting to consider is the possibility that within many species a similar set of pathways is involved in the suppression of reproductive axis activity, but that differential activation or inhibition of specific pathways within this complex is dependent on the specific stress experienced, as well as within a specific species. A great deal more work is needed in this field to dissect the neural mechanisms underlying behaviorally induced reproductive dysfunction and how this varies with the type of stress and with species.

Individual Susceptibility to Stress-Induced Suppression of Reproductive Function

A concept that arises again and again in this area of investigation is that in most all species some animals appear to be more susceptible to the stress-induced

suppression of reproductive function than others. As discussed in this article, subordinate social status is associated with a greater inhibition of the reproductive axis, either in response to an imposed stress or in the normal living situation, in a diversity of primate species, including rhesus monkeys, cynomolgus monkeys, baboons, talpoin monkeys, and marmosets. A difficult question to answer that needs to be addressed in future studies is whether these animals are intrinsically more susceptible to stress-induced reproductive dysfunction or whether they experience more stress and thus have greater inhibitory drive to their reproductive axis.

Summary

As detailed in this review, both short- and long-term exposure to a variety of psychological and social stresses can suppress reproductive hormone secretion and lead to a decrease in reproductive behaviors and fertility in a number of nonhuman primate species. Although there appear to be some species differences in the degree or route of inhibition of the reproductive axis caused by exposure to such stresses, there also appear to be several general principles that are common to most species. Perhaps most important of these is the concept that the effect of a particular stress at a particular time on the reproductive axis of an individual animal can be modulated by a great number of variables. These modulating variables include social status, the magnitude and duration of stress, perception of the stress, aggressive behavior, seasonal cues, and the prior level of activity within the reproductive axis (see [Figure 1](#)). Thus, although it is possible to measure group mean responses to specific stresses and make conclusions about the effect of a stress on the reproductive axis in that species, such a mean assessment may be of little use in determining whether an individual animal will experience a suppression of reproductive function in response to that stress. An increased understanding of the mechanisms by which psychological and social stresses suppress the activity of the reproductive axis may well be achieved by focusing future studies on these individual differences in response to stress.

Glossary

<i>Intellectualization</i>	The use of intellectual activities to exert control over anxiety and reduce tension. This proclivity is often encountered as a defense against instinctual drives in adolescence and is enlisted as resistance in insight-oriented therapy.
<i>Psychoanalysis</i>	A discipline discovered by Sigmund Freud which is (1) a psychotherapeutic technique, (2) a systematized theory of human behavior including development and (3) a method of investigating the mind.
<i>Resistance</i>	A familiar but paradoxical phenomenon in psychotherapy and psychoanalysis. The patient, having entered treatment, opposes the process in ways which can be conscious, pre-conscious or unconscious.
<i>Transference</i>	The displacement of patterns of feelings originally experienced in childhood onto a person involved in a current relationship.
<i>Transference resistance</i>	The usually unconscious use of transference affects as a resistance to therapeutic progress.

Introduction

By the time people consult a mental health professional for relief from the consequences of stress, they are usually highly motivated. Psychological suffering; anxiety and depression; and loss of functions such as the inability to work, engage fully in interpersonal relations, or care for themselves have often reached profound levels. It is remarkable, then, to discover that many patients also resist treatment and that such

opposition is a reliable phenomenon that can be expressed in a whole universe of behaviors. The patient may be silent, withhold essential information from the therapist, flood the sessions with intellectualizations or dreams so that reporting consumes all the time, arrive late for appointments or fail to come, delay paying the fee or refuse to pay at all, and find it impossible to follow directions about medications. Many additional forms of resistance have been reported, including eagerness to make the best use of the time in the sessions, “talking over the treatment every day with some intimate friend,” what Freud called a “therapeutic leak,” using evasive speech (or lapsing into technical jargon) or clichés, or mumbling and accusing the therapist of suggesting ideas too strongly. There is also documentation of resistance as it occurs in the termination phases of psychoanalysis in children and in adults.

Patients can be aware of resistance, but often they are not; that is, resistance may be conscious, preconscious, unconscious, or a mix of all three. Regardless of the etiology, resistance tends to be most pronounced in the insight-oriented psychotherapies, those aimed not only at symptomatic relief but also at self-knowledge.

Definitions

In *The Interpretation of Dreams*, Freud was crystal clear: “Whatever disturbs the progress of the work is resistance”; this concept is still current. Stressing that resistance is ubiquitous and pervasive, Moore and Fine (1990: 168–169) also point out that “analysis of resistances . . . has become a hallmark of psychoanalytic treatment.”

Resistance as a Defense

In psychoanalysis, the most ambitious form of psychotherapy, patients are often unconsciously anxious about revealing themselves, dreading possible rejection by the analyst. They may also fear health itself as alien, dangerous, and possibly more menacing than being sick.

Under such circumstances, almost anything can be drafted to slow the process of change, as the lists described earlier attest. In addition, patients may treat the therapist as an enemy and alternately comply with and rebel against his or her presumed wishes; for example, some patients report memories or dreams but cannot work with them via associations. Among the feelings defended most keenly are those toward the therapist (i.e., transference resistances), but unconscious resistance may also be evoked in the analyst or therapist

and these constitute a manifestation of countertransference problems. These can interfere with the therapist's ongoing empathic resonance with the patient, resulting in technical misjudgments such as inappropriate content or timing of interpretations.

Resistance Resulting from Shifts in the Therapeutic Alliance and as Distinct from Negative Therapeutic Reaction and Negative Transference

Because it is pervasive, resistance should be clearly distinguished from other therapeutic phenomena, such as negative therapeutic reactions or negative transference. According to Moore and Fine (1990: 168–169), a negative therapeutic reaction is a “clinical response. . . . Following a period of what seems to be constructive and effective therapeutic technique and understanding, the patient's condition paradoxically worsens.” Freud's position was that “Every partial solution that ought to result . . . in an improvement or a temporary suspension of symptoms produces . . . for the time being an exacerbation of (the) illness.” However, when the patient sees the therapist as malevolent, exploitive, or manipulative, these are negative transference feelings.

History

Sigmund Freud is generally credited with the identification and explication of resistance in contemporary psychological thought. His first mention of the entity came in a discussion of Elizabeth von R., a patient who was sent to him in the fall of 1892 and became his “first full-length analysis of a hysteria.” Instead of using hypnosis, as he had previously in his work with Josef Breuer, Freud encouraged this patient to associate freely, to say whatever came to mind. When she was silent and he inquired what was going on in her head, she replied, “Nothing.” Freud refused to accept this answer, believing that it was the same species of willful forgetting that had caused her hysterical symptoms in the first place.

Another patient, the obsessional neurotic known as “the rat man,” began treatment in late 1907. This man described the conflict that results in resistance by quoting Nietzsche to Freud: “‘I did this,’ says my Memory. ‘I cannot have done this,’ says my Pride and remains inexorable. In the end – Memory yields.” Describing a kind of punishment practiced in Asia, the patient rose from the couch and begged Freud not to insist that he go on. Freud explained that “The overcoming of resistances is a law of the treatment” and helped him to finish the story; the perpetrator was tied down, a pot with rats in it was turned upside down on his buttocks, and the rats bored their way into his anus.

By 1912 Freud was confident enough to emphasize the pervasiveness of the phenomenon: “(It) accompanies the treatment step by step. Every single association, every act of the person . . . must reckon with the resistance . . . (and it) represents a compromise between the forces that are striving towards recovery and the opposing ones.” Everything that distracts the patient from following the fundamental rule of free association is an obstruction.

Implications for Technique

Because resistance is a dramatic and undeniable example of the operation of the unconscious, its appearance can signal when therapeutic work is approaching painful and important areas of the illness. Such nodal points are often thick with cues about the etiology of the neurosis, and tact and timing are essential when attempting to bring the resistance to the patient's awareness. Careful and accurate interpretations at this point can inform both participants greatly and free up the therapeutic log jam.

Implications for Theory

At first thinking that resistance was simply an automatic defense, Freud saw it chiefly as an obstacle to the work. However, as the implications and extent of unconscious resistances became clearer, these led Freud to reconsider his topographic model of the psyche as the relationship of conscious, unconscious, and preconscious mentation and to incorporate these concepts into a new stance that stressed a structural view of the mind as composed of the id, ego, and superego.

One good way to grasp how profoundly the discoveries about resistance changed psychoanalytic theory is to contrast the taxonomies Freud used to categorize them. In 1895, he thought resistances appeared under three circumstances: (1) if “there is a personal estrangement . . . if the patient feels that she has been neglected, insulted, too little appreciated,” (2) if the patient dreads becoming too dependent on the physician or influenced by him, or (3) if the patient is frightened at finding “she is transferring on to the figure of the physician the distressing ideas which arise from the content of the analysis.” Coincidentally, this discussion marks the first use of the term transference in the psychoanalytic sense.

Twenty-eight years later in a famous passage, Freud found he required a five-tier classification system. Three species of resistance came from the ego – repression, resistance, transference resistance – and the unwillingness to renounce the gains of being ill was “an assimilation of the symptom into the ego.”

Id resistance, approached by “working through” the analytic discoveries, and superego resistance completed the list. The latter, “the last to be discovered, seemed to spring from guilt or the need for punishment and opposes every move toward success.”

Current Views

The understanding of resistance has remained a salient feature of psychotherapy and psychoanalysis and a prominent focus of psychoanalytic technique. However, with the epigenesis of post-Freudian theories, each school has proposed new ways of thinking about the etiology of resistance and offered corresponding technical recommendations for dealing with it.

Self-psychologists believe that resistance is evoked by failure of the therapist’s empathic attunement and that such failure will mirror the narcissistic patient’s early deprivation. Object relations theorists stress the extent to which resistance occurs when there has been insufficient recognition of the real as well as the unique transference relationship between the therapist and the patient. Brenner’s revised structural proposals see resistance mainly as a defense that is a compromise formation in the patient’s conflict between wishing to recover and wishing to remain ill. Schafer feels that resistance can be traced to insufficient understanding of transference–countertransference currents as these occur in analytic work.

Recent Research

The explosive proliferation of research in the neurosciences and the deepening sophistication of findings in cognitive psychology have profound implications for clinicians facing resistance in their daily work. There are venerable journals in each area, but they are not notably accessible to the others and few acknowledge or attempt to integrate the contributions from all three areas. *Neuro-psychoanalysis* is one of the most scholarly and useful of a group of new journals whose aim is to do this. First published in 1999, it is staffed by large and distinguished editorial boards in neuroscience and psychoanalysis. The lively ongoing disagreements in this journal and the roster of established experts as authors testify to the relevance of neuroscience to analytic and dynamic psychotherapeutic work and simultaneously to the triangulation of cognitive psychology, neuroscience, and psychotherapy.

For example, recent research in cognitive psychology has underscored the importance of continuity in forming psychological constructs and offers an appealingly quantitative explanation of the fact that resistance that disrupts continuity (i.e., missing

sessions or coming late) can delay or even disrupt therapeutic progress. The experimental demonstration that remembering itself can cause inhibition suggests that when patients’ recovery of important memories falter and transference constructs might be invoked, the therapist could also benefit from information from relevant cognitive principles that would enrich understanding the difficulty and inform technique.

Clinician–researcher–scholars capable of interdisciplinary synthesis are rare but not unknown. In a 2003 summary of his work, for example, Levin illustrates the importance of learning in psychotherapy and the links among learning, psychoanalysis (especially but not exclusively transference), and the neurosciences, an emphasis he has espoused for decades. Citing recent research findings, he suggests using these to augment existing ways of thinking about resistance – that resistance occurs because “patients defend themselves against more novelty than they can process at a given time” (Levin, 2003: 82), a cognitive and neural overload.

Conclusion

The importance of the patient’s resistance to treatment has escalated as the disciplines of psychotherapy and psychoanalysis have matured and become theoretically and technically more diverse. However, the observation that there are obstacles to cure has remained consistent, as has the indefatigable work of finding more effective ways to understand and clear away these barriers to progress.

Methods of Restraint

Stressor Intensity

Stressor Parameters

Glossary

Chronic stress state A persistent presence of physiological and psychological symptoms of the stress response following exposure to an extreme stressor.

Inescapable stress A stressor that is delivered to an animal whereby it cannot escape or avoid by performing any particular behavior.

Methods of Restraint

Loose Restraint

A method of restraining an animal so that free movement is restricted, yet some movement is still possible. Loose restraint is often used in conjunction with other procedures, not necessarily related to stress research, where it is necessary that the animal's movements be minimized, e.g., while taking a blood sample or administering an injection. In rodents, loose restraint is usually accomplished by placing the rodent in a small chamber or in a cloth. In nonhuman primates, restraint is accomplished by making the size of an individual cage smaller.

Tight Restraint

This method completely eliminates an animal's ability to move. Techniques for rodents include jacket or harness restraint or securing the rodent's limbs as it is lying prone. For nonhuman primates, tight restraint is accomplished by placing the subject in a chair with straps attached.

Supine Restraint

A variation of tight restraint for rodents in which the animal is tied down while lying on its back.

Combination Restraint Stress with Other Stressors

Restraint stress is combined with another type of stressor such as cold, heat, water immersion, and electrical shock to the tail.

Stressor Intensity

Hans Selye performed the pioneering work with restraint stress. The use of restraint, as an experimental procedure, was initially developed by Serge Bonfilio in France and by David Brodie in the United States. Subsequently, restraint stress has been utilized extensively, alone or in combination with other stressors, in order to measure its physiological, psychological, and pharmacological effects. Similar to pharmacological studies, the capacity of a particular treatment to produce a credible effect is reinforced by what is known as the “dose-response” relationship. The basic tenet of this relationship is that increasing doses of a particular treatment elicit increasing degrees of that treatment’s effect. Therefore, based on integrated stress research spanning the fields of psychology, neuroscience, endocrinology, immunology, gastroenterology, cardiology, and pharmacology, one may grade a particular stress protocol’s “dose” or intensity. In their two comprehensive reviews of the restraint stress literature, Paré and Glavin have provided the means to gauge the intensity of various experimental manipulations, including the parameters of restraint type, duration of restraint, and number of stress episodes, among others. Intensity is verified through associated effects on behavioral and physiological stress respondents. Thus, the methods of restraints can be graded as combination > supine > tight > loose.

Stressor Parameters

Duration of Restraint

While the type of stress most accurately predicts the intensity of a stress episode, the duration of the episode can greatly affect its intensity as well. In general, increasing the duration of a particular restraint session

increases the degree of stress-associated symptoms. However, with the milder restraint types (loose restraint), longer duration bouts may be associated with decreased responsiveness—evidence of habituation.

Number of Restraint Episodes

As with the duration of a restraint session, increasing the number of sessions has the general effect of inducing more pathological consequences. However, this generalization is qualified by studies demonstrating diminished physiological responsiveness with multiple stressful episodes.

Other Factors

Several factors will influence the degree or duration of stress responses to restraint greatly.

1. Gender: pathophysiological consequences from restraint stress are more apparent when restraint stress episodes occur in the activity phase of estrus as opposed to the inactivity phase.
2. Cycles: the effects of restraint stress appear to differ as a function of time of day and season.
3. Age: although the amplitude of glucocorticoid responses in aged rats does not differ from young rats exposed to restraint stress, the duration of these elevations is longer in aged rats.
4. Strain: some rat strains (e.g., Wistar-Kyoto) are more vulnerable to the effects of restraint, whereas others are more resistant.

Revenge Fantasies

M Horowitz and S Meffert

University of California, San Francisco, CA, USA

© 2007 Elsevier Inc. All rights reserved.

Biological Issues

Social Issues

Psychological Issues

Treatment Issues

Conclusion

Revenge fantasies have been an important human activity since the beginning of recorded history. The Bible, Shakespeare, novels, and modern television and movies motivate their characters with fantasies and plans for seeking vengeance. The more traumatic an experience, the more intense are the revenge fantasies. Everyone is so familiar with revenge fantasies that there is no need to review their many forms. What is of concern is how to control revenge fantasies, how to reduce preoccupation with them, and how to prevent maladaptive action.

Biological Issues

The theme of revenge fantasies is so pervasive in human history, so common throughout populations that it seems to function almost like an instinct or drive. There is an adage that revenge is a dish best served cold. The indication of a biological function is not that revenge is cold; rather, it is a hot thirst that seems to be slaked when the revenge is taken. Animals other than human beings may take a revenge for a recent attack. Whenever a human being is caught up in a primal revenge action plan it is possible to use higher psychological processes to increase self-governance and to provide social organizational structures to prevent damage.

Social Issues

Genocidal campaigns are usually based on propaganda that incites bloodlust on the basis of revenge fantasies. General secular values are needed to counteract some fundamentalist religious values that indicate the need for blood revenge, as in killing whole populations. The evolution of society itself shows this history over several centuries. Social schemas of understanding and compassion have been used for this purpose. Our focus is mainly on psychological issues, so we comment here that, after a traumatic experience shared by a population group, it is important to

emphasize to that population what is adaptive and maladaptive in terms of themes of retaliation versus those of adequate compensation or preparation so that the catastrophe will not happen again.

As recently noted by the World Health Organization, there is a divide in humanitarian aid services between mental and social health, particularly around the issue of trauma. Many debates have centered on the idea that posttraumatic stress disorder (PTSD) requires an understanding of individual pathology and that treatment that should be indexed to a particular culture, population, and era; critics argue that PTSD diagnosis and treatment are therefore not generalizable, particularly not across cultures. Such debates have become so heated that humanitarian aid efforts often have to choose between using individual, trauma-based mental health treatment and broader psychosocial public health-oriented treatment to address community-level mental health problems. The problem with splitting treatment into individual and social components is that it may obscure their heavily intertwined nature by compartmentalizing them into separate categories.

One of the most potentially destructive aspects of trauma is the impulse for retaliation that follows. The tragic aspect of this impulse is that it is much more often enacted against the close social contacts of the traumatized individual than the original aggressor; although the focus of revenge fantasies may be the hated enemy, the target is often loved ones, such as spouses and children. Research with Vietnam veterans shows that veterans with symptoms of psychological trauma are at high risk of committing violent acts toward their spouses and children.

One horrifying tactic of warfare capitalizes on this feature of human nature by raping enemy women or women who belong to the same social group as that of the enemy. This appears to be calculated not only to infect bloodlines; humiliate, torture, and sometimes kill the victim; but also to destroy social bonds in the enemy group. The rapists understand that the desire for revenge and anger against the group they represent will cause the community to reject the raped women from their social roles of wife, mother, and relative. The rapists count on the idea that feelings of anger and revenge will triumph over the social bonds of love and affection, leading to the internal destruction of the community. Unfortunately, they are often right.

Psychological Issues

Emily Dickinson may have led her cloistered, unmarried, and childless life because she felt betrayed. She became preoccupied with love and death in her poetry; in which she could only fantasize revenge. Here, for example, is her poem #339F.

I like a look of Agony,
 [perhaps the look she would like to imagine on the
 face of this man]
 Because I know it's true
 [not false seductive expression, which she may have
 felt lured by]
 Men do not sham Convulsion
 [meaning the signs of suffering, although they may
 feign love]
 Nor simulate, a Throe

 The eyes glaze once – and that is Death –
 [she is imagining as she writes that this man's death
 was painful, as he deserved]
 Impossible to feign
 The Beads upon the Forehead
 By Homely Anguish Strung

One of the worst betrayals is when a trusted person exploits us. In modern days, some men insist on going bareback into intercourse (i.e., they refuse to use a condom). Some do so knowing that they risk transmitting a disease they know they have. The sexual partner finds out later that he or she has been infected with human immunodeficiency virus (HIV), hepatitis C, syphilis, gonorrhea, chlamydia, or genital herpes. Revenge fantasies then become a frequent compensation and sometimes a violent enactment.

The recipient of the disease may have felt love but that turns to hate. Revenge fantasies accumulate; forgiveness is beyond imagination. Still, the goal is to avoid violence or identifying with the selfish lover. Struggling to master a betrayal does not mean either taking revenge or giving up any course of compensatory action.

An effective response to a trauma is a course of action that may create more good than evil. Telling a community circle about the bareback perpetrator does so because it may prevent similar crimes. But figuring out the differences between a maladaptive hunger for revenge and an effective course of action is difficult. Expressions from the Bible such as “an eye for an eye, a tooth for a tooth” are uttered frequently. In our contemporary understanding of this language, they have a bloody, excessive connotation, which was not meant when the text was written. Then it meant do not annihilate or destroy the betrayer excessively but rather take a measured and reasoned course by retaliating by taking only an eye for an eye or a tooth for a tooth. In other words, do not massacre.

The perpetrator of a trauma that leads to revenge fantasies is seldom a total monster; we can try to understand his motives. Having some understanding does not mean blindly trusting the same abusing person or group again. Revising beliefs and values can lead to increased skill at seeing other humans as blends of good and evil, caring and selfishness. We get better at reading their intentions and learn when and how to be self-protective.

This work of reviewing memories of a trauma or betrayal can be painful. Intense negative emotions are rekindled. The strength of revenge fantasies may lead to repeated intrusive episodes, making it hard to concentrate our attention elsewhere. Our anger, fear that no one can be trusted, and despair over the coldness of the world can cause us to feel bitter or to impulsively engage in acts of hostility. Sometimes our aggression is displaced on to some weaker target. The crippling interpersonal effect of revenge fantasies is that, whether fulfilled or not, they often result in more destruction of those we love than of our despised enemies. Such venting leads to guilt and shame.

How can we avoid recycling trauma and revenge that causes further trauma in this manner? Thinking of a betrayal over and over again, without progress in healing; only increases bitterness and diminishes our chances at happiness. Our goal must be a point of completion in our processing of the memory. This may involve efforts to achieve a new more correct and realistic judgment. A plan for making a measured response at the right target or at no target can result.

A memory of an injury or an insult is fertile ground for growing a seed of rage into a towering weed that can strangle love and compassion. Some people or some groups always seem to carry a chip on their shoulder; they expect frustration from others and even nice gambits from others can be twisted and become misinterpreted as not enough. They feel as if the whole world has already betrayed them and refuses to make up for it. Each new betrayal reinforces this irrational attitude.

Seething with anger does have an energizing function because possessing targeted anger often makes us feel strong, whereas fear makes us feel weak. That is why states of self-righteous indignation are so popular on talk radio and why the revenge ideas are easy to sow and hard to give up.

After a betrayal, a person with such character traits of bitterness and resentment often enters a state of self-righteous indignation and then stays in this state because it feels like energy or fuel for the self. The burning anger helps such people feel more solid instead of feeling frail, empty, or apathetic. Breaking free of such snags is difficult. We can, however, learn to recognize the trap and step away from it. With the

recognition that we can be strong without being in a self-righteous rage, we can begin to analyze the situation rather than replaying an endless loop of revenge that goes nowhere.

A character trait of bitterness can result from unfortunate experiences in childhood or adolescence. Rightly or wrongly, many children regard their parents as omnipotent and so blame their parents for any suffering they felt as a consequence of unfortunate events. Any new frustration that occurs in their adult lives just adds to the trait of bitterness.

Treatment Issues

There are many evidence-based treatments for depression and anxiety, yet there remain very few treatments for the anger and interpersonal violence that often stem from trauma and revenge fantasies – with the exception of dialectical behavioral therapy, which generally aims to treat anger that results in self-harm. Violent behavior and the enactment of revenge fantasies often find their treatment, or lack thereof, in the criminal justice system, sometimes with court-mandated anger-management programs, for whose success there is little empirical support. Many factors may contribute to this situation, one of which could involve a conflicted attitude that society has toward anger, violence, and revenge. Particularly with cultural constructions of masculinity, the qualities of assertiveness, forcefulness, and even a measure of anger or the implication of violence are sometimes valued as reflecting ambition, competence, or efficiency in achieving life goals. Hollywood, of course, is a frequent purveyor of these stereotypes, with the hot-tempered violent hero with a chip on his shoulder from some previous wrong. These concepts stand in contrast to other cultural norms, such as the many aphorisms and maxims that underscore the destructive effects of anger and revenge.

As an adult, a person can realize the truth of parental limitations. These limitations, seen through adult mindfulness, are usually different from adolescent visions of how bad the parents had been. As a child, the person regards a parental lapse as being done on purpose. As an adolescent, he or she may show contempt for grownups. As an adult, the person can revise his or her entire internalized story of what happened and the explanations for how and why it happened. For example, a mother's depression and substance abuse can be seen as a terrible difficulty and struggle rather than as a deliberate abandonment of a child.

The story of a person's own life can be revised in the direction of having more sympathy for, and less blame toward, parental figures. This does not mean

memories and attitudes toward parents are changed to happy ones. Many adults had unerasable childhood tragedies and or deficiencies in parenting. On adult reflection, there may be a realistic appraisal of the past events, but that realistic version may still fall far short of some ideal or even good-enough parenting.

Realistic appraisal may lead to sadness, even a delayed mourning for childhood losses. The person must mourn a childhood that cannot ever be repeated with a healthier-minded parent. Passing through that grief makes the person ready to seize what the here and now might provide and to look to the near future for what is possible. New, warm, loving relationships in various areas of one's life can help one to heal the wounds of childhood. The person learns to forgive him- or herself because the person was not to blame, as he or she might have supposed as a child, and to forgive others for the neglect they could not prevent.

Suppose the person had an abusive and neglectful father, became bitter, and now unconsciously hoped to find an ideal father as an adult. The person hopes that new candidates will make up for the damage done in the past, but they all turn out to fail the mission. At first, the new candidate for caring seems amiable and supportive, but the good qualities fall far short of the person's immense expectations. Sometimes others are provoked to fail; an otherwise inexplicable hatred is then felt toward the contemporary nice person and the inappropriate anger ruins the relationship. Efforts to change can stop this vicious cycle and reduce even the character trait of being constantly bitter.

The general wisdom of pursuing forgiveness does not condone neglect or abuse; it simply understands the humanness in all parties. The person avoids demonizing the targets of his or her moral indignation. Compassion is sought, but this does not mean passive resignation to enduring wrongs. Turning the other cheek may only invite more slaps in the face.

Giving up self-righteousness is not the same thing as giving up moral indignation. Moral indignation is a response to seeing people break rules when they could follow them. A good person can use moral indignation and do something to prevent evil and promote compassion or virtue. He or she may use moral indignation to gather a like-minded group together to encounter and counteract the exposure of children to abuse or neglect. This kind of indignation is effective and adaptive, whereas chronic bitterness with revenge fantasies is inefficient and maladaptive.

After experiencing an intense trauma or betrayal, the person has to ask him- or herself whether the perpetrator is a friend, an enemy, or perhaps an unreliable narcissist. The person modifies his or her expectations according to a realistic appraisal. The

person must learn to recognize enemies only when they exist. Even in these situations, the best aim is to temper wrath with reason because the sword of destructiveness often cuts backward.

It is helpful to ask questions. Why did the enemy attack or deceive? How was I harmed? If I counter-attack, what are the likely consequences? How does a cycle of betrayal, attack, and counterattack end? In answering these questions, the person finds that the extreme of an ideal self and a demonic enemy is almost always wrong. The person must clarify more realistic central appraisals.

Suppose there is a persistent enemy. One ideal scenario is to trust in a truce based on a pact of non-belligerence. Can a person realistically find a way so that the enemy will respect the rules? In the dreaded train of thought, the enemy is divested of human qualities and is viewed as a constantly malignant force. In an ideal train of thought, the enemy keeps his or her word of honor. These opposing extremes set the stage for a moderated train of thought. The rational analysis does not automatically arrive at truce or warfare. The enemy may remain the enemy. The rational appraisal leads to preparation for defense and continued alertness to signs of increasing danger. It rejects an attitude of unending battle and vendettas. It sets up bad consequences for breaking a truce and good consequences for keeping it. The person may fight the enemy but plan to accept the enemy's child.

Conclusion

The best adage ever coined against brutality is the golden rule: do unto others as you would want them to do unto you; do not treat others as you would not want to be treated. An excellent quality of such adages is that they can become a socially shared morality or ethic that can be taught by any religion or culture.

A new adage might be: when you feel bitter, seek the good. This adds something to existing popular adages such as: perform random acts of kindness and senseless acts of beauty. Usually people want to do good when they feel good or are in love. The goal is to do good when we are less elated. The idea of bringing goodness into the world when we feel demeaned, insulted, angry, and frustrated is a useful one to highlight because this stance can counteract self-righteous rage and revenge impulses.

This attitude – when you feel bitter, do good – counteracts two normal but malignant responses to

being insulted. One response is to cave in and feel weak, deflated, and degraded; the other is the opposite, a result of role reversal, to adopt a strong menacing role from which to lash out at others who are weaker. For example, a child who sees a civil war squad murder his parents may well grow up to become a civil war soldier ready to commit similar atrocities or worse.

Adages help keep us alert, so here are some other versions. When you feel bitter, do good. Do not wait until you feel good to act with compassion for others. Protect others as you want to be protected. The best cure for an enraged heart is comforting others. Do not pass hatred on; fight it with compassion.

Profoundly Complex Patterns of Stress Responses

Stressors Related to the Physiopathogenesis of Rheumatoid Arthritis

An Evolving Research Challenge in Rheumatoid Arthritis

Summary

Glossary

Ankylosing spondylitis

A form of arthritis mainly affecting the spine and sacroiliac joints and, to a lesser degree, those of the girdles and lower extremities. A striking association occurs with the genetic factor HLA-B27 and familial aggregation is strong. Mechanisms remain obscure, but typical enthesopathic lesions suggest that biomechanical stresses could activate inflammatory pathways in its physiopathogenesis.

Biomechanics

The study of the application of mechanical laws and the actions of internal or external forces upon the living body or its structures. Biomechanical forces are believed to be important contributors to a number of rheumatic disorders, especially ankylosing spondylitis and osteoarthritis.

Central sensitization

A biopsychological process whereby sensory signals or stimuli are amplified in intensity with expansion of the receptive fields through central nervous system (CNS) mechanisms.

Central sensitivity syndromes

Chronic, noninflammatory rheumatic disorders believed to constitute an interrelated or overlapping family of symptomatic and dysfunctional conditions. The causes are unknown, but may result from central sensitization mechanisms and may be amplified by environmental, personal, or socioeconomic stresses.

Enthesopathy

A pathological process occurring at sites of attachment or insertion of joint capsules, ligaments, or muscle tendons into bony tissues, which is typically found in ankylosing spondylitis and related spondyloarthropathy conditions.

Fibromyalgia syndrome

A common and prototypic example of the family of central sensitivity syndromes. It is defined by widespread pain and the physical examination finding of multiple foci of localized tenderness on firm palpation at characteristic points (tender points), particularly of myofascial tissues. Pain, stiffness, and systemic symptoms of poor sleep and fatigue, anxiety or depression are often aggravated by insufficient or excessive physical activity and by environmental, personal, or socioeconomic stresses.

Microvascular endothelium

The single cell lining layer of the luminal surface of the microvascular system, which regulates transport of macromolecules and blood components into the interstitium. Endothelial cells are regulated by the neuroendocrine and immune (NEI) systems and contribute to inflammation by their activation leading to enhancement of inflammatory cell migration from the lumen into the interstitium, and by their secretion of mediators of inflammation.

Osteoarthritis

The most common form of arthritis, particularly in older ages, which results from biomechanical stresses and biochemical changes that damage articular cartilage and also cause lesions in the surrounding osteoligamentous tissues of the joint. The process may be either primary resulting from chronic excessive repetitive joint impacting or secondary to gross trauma or inflammatory arthritis conditions. Weight-bearing joints are mainly affected and it is often referred to as degenerative joint disease.

Physiopathogenesis

A process which progresses from chronic disordered physiology or dysregulated function of organs or systems (presymptomatic phase) to later stages of pathological, symptomatic disease states. The implication of this term is a transition from initial chronic physiological dysregulations (preclinical phase) to later clinical disease states. Alternatively, the term, pathophysiology, implies that initial pathological processes alter physiological functions secondarily. Bidirectional derangements often occur in many diseases, but to differing degrees, and depending upon the phases of the processes.

Rheumatoid arthritis

A chronic systemic disease primarily affecting small joints of the extremities in a symmetrical fashion and characterized

Rheumatic disorders

by inflammatory changes in the synovial membranes. Without effective therapy, the pathological process extends beyond the synovial tissue and inflammation erodes adjacent joint cartilage and bone, leading to deformities and disability. The presymptomatic causes of this disease leading to inflammatory pathways are unknown, although such pathology predominates in the clinical phase. Women are affected about three times as often as men, which is opposite to ankylosing spondylitis, and is an important clue to respective predisposing mechanisms.

The general nosological term for conditions affecting the musculoskeletal system that include symptoms of pain, stiffness, and other related abnormalities pertaining to joints or nonarticular (myofascial) structures. These disorders include a wide variety of conditions characterized by degeneration, inflammation, or metabolic derangements of connective tissues, joints, or other musculoskeletal structures

Spondyloarthropathy disorders

A group of overlapping arthritic diseases affecting extremity or sacroiliac joints and the vertebral spine to varying extents. Ankylosing spondylitis is the prototypic disorder in this group that mainly affects the sacroiliac joints and the spine, but can also involve lower extremity and girdle joints. They share clinical and radiological features, particularly enthesopathy lesions and increased presence of the cell surface HLA-B27 antigen marker.

Introduction

Historical Contributions to Stress Concepts

Modern concepts of regulatory biology may be traced to Claude Bernard (1813–78), who pioneered the doctrine of a constancy of the *milieu interieur*. Walter Cannon (1871–1945) further promoted and broadened the concept of physiologic organization and regulations, especially in his 1929 report on homeostasis. That original concept referred to an ideal setting of effectors controlling the *milieu interieur*. However, modern concepts of homeostasis infer the occurrence of different settings of the effectors as well as the accumulation of stress impacts or allostatic load on the physiological control mechanisms. The paradigm of allostatic load proposes that stress mediators have protective as well as damaging effects on the organism. The accumulation and overexposure of the body to stresses can promote adverse effects on various systems by the mediators.

In the next decade, Hans Selye (1907–82) developed experimental (rodent) models of generalized stress reactions to noxious agents. He demonstrated opposite changes in the thymus (atrophy) and adrenals (hypertrophy) as part of the organism's responses to injuries and chemical intoxications. Those experiments revealed counterregulatory relations between the hypertrophy of adrenal glands and involution of lymphatic tissues, which he originally considered to be nonspecific.

In 1946, Selye published his synthetic theory of the general adaptation syndrome and diseases of adaptation. Relative adrenal insufficiency was proposed to be a contributory factor in stress-related or immunologically mediated diseases. Selye's research and that of others indicated that the adrenal glands are closely connected with the organism's resistance to noxious stimuli or stresses.

In humans, adrenal gland enlargement was recognized to result from a wide variety of conditions, including those of increased physiological demands (pregnancy, cold exposure, exercise, and low oxygen tension), hypermetabolic disturbances (hyperthyroidism, and excessive insulin administration), infections, burns, and other shock-producing states as well as multiple toxic drugs. The concept of stress reactions became recognized largely under Selye's influence. His theory offered a unifying mechanism to interpret complex sets of metabolic, psychoneurophysiological, immunological, and other adaptive changes that characterized responses to a wide variety of noxious or perturbing stimuli.

The above-mentioned and other concepts of stress biology will be related to selected examples of rheumatic disorders. Human stress responses are profoundly complex, but their diverse impacts may be inferred to contribute to symptoms, physiopathogenesis, or outcomes of particular rheumatic disorders.

A Broad Spectrum of Rheumatic Disorders

Rheumatic disorders encompass a broad spectrum of conditions which affect the musculoligamentous (myofascial) and skeletal structures of the body as well as other soft connective tissues and internal organ control systems. These conditions include over 100 medical diagnoses. The diseases usually have defining clinical features, which vary in patterns of pain, psychological behaviors, limitations of movements, localizations of inflammation, or structural involvements in the body. The patterns of symptoms or pathology result from varied, but often overlapping primary or secondary pathways in the causations of these diseases. Classification of these different disorders is often based upon defining symptoms or clinical patterns, rather than upon specific etiology.

Nosology of Rheumatic Disorders and Potential Stressors

The term, rheumatism, is derived from the Greek *rheuma*, flux, inferring that symptoms or manifestations can *flow* from one part of the body to another. The expanded classification of *Arthritis and Rheumatic Diseases* is the overriding medical label for this broad spectrum of conditions and diseases. The role of stress in such a large number and diverse patterns of rheumatic disorders cannot be fully addressed in this limited review. Particular examples and principles of stress reactions affecting this family of conditions are offered. Research indicates that the general population is often exposed to physical or psychological stressors, which vary considerably among individuals and subgroups. The patterns of stressors tend to relate to particular rheumatic disorders, presumably via their respective mechanistic pathways. Examples of types of stressors affecting rheumatic diseases are provided.

Prototype Rheumatic Disorders and Stressors

Features of Fibromyalgia Syndrome

A type of noninflammatory rheumatic condition associated with stress mechanisms is fibromyalgia syndrome (FMS). This disorder is manifested by musculoligamentous (myofascial) pain, fatigue, nonrestorative sleep, affective features, and decreased functional ability. This condition is an identifiable clinical entity, despite the absence of objective physical deformity, inflammation, or structural lesions. Its clinical symptoms follow rather characteristic patterns. Its course tends to be associated with the degrees of subjectively perceived stresses or objectively experienced physical aggravating factors. The causal pathways of FMS are unknown, but are believed to involve central nervous system (CNS) and autonomic nervous system (ANS) activation and sensitization. The more prominently implicated stressors are believed to operate via these physiological pathways.

The particular stress factors which aggravate FMS differ in individuals, perhaps due to their predispositions and personalized circumstances. They include variously described stresses in personal relationships, demands of daily living as well as particular environmental or occupational hardships. Additional individualized stressors include cold or unusually warm temperatures, trauma, physical impacting or other biopsychological stresses, and biomechanical strains on the body. Data suggest that sufficient intensity of stress can cause central sensitization, as reflected in posttraumatic stress disorder (PTSD).

FMS is believed to be but one recognized clinical entity in a family of central sensitivity syndromes. These disorders compose a spectrum of clinically overlapping and co-occurring noninflammatory conditions. They frequently manifest with myofascial pain, fatigue, nonrestorative sleep, hypersensitivity to various stimuli, and affective features. The conditions are somewhat diverse, involving different systems, but tend to have overlapping physiological stressors and aggravating environmental or occupational factors. Criteria have been developed to classify the particular syndromes, based upon relatively defining clinical features.

Features of Rheumatoid Arthritis

The main inflammatory rheumatic condition believed to be affected by stress mechanisms is rheumatoid arthritis (RA). This disease is characterized clinically by pain, objective swelling, and inflammatory damage in multiple extremity joints (i.e., polyarticular) in a symmetrical pattern. Blood samples of RA patients clearly show evidence of systemic inflammation. Increased levels of biomarkers (e.g., acute phase proteins) and mediators of inflammation (e.g., inflammatory cytokines) are found in the blood and joints during active phases of this disease.

In genetically susceptible people, the underlying systemic mechanisms believed to be operating in RA are dysregulations of the neuroendocrine and immune (NEI) as well as the microvascular endothelial (MVE) systems and their interactions. The more specific stressors are believed to further perturb the already dysregulated NEI and MVE systems or place increased demands upon joints. However, CNS-mediated psychosocial stresses also affect pain behaviors and disease activity in RA, as may occur generally in other disorders.

Stressors of the RA clinical status include particular physical (e.g., overuse of joints) or subjective (e.g., poor sleep and fatigue) factors as well as systemic circumstances, which overtax the physiological balance or energy reserves of the body. Aggravating or stressor factors can increase both symptoms and objective manifestations of RA. Such stressors are believed to operate via enhanced perturbations of the already dysregulated physiopathogenetic pathways in RA as well as by greater direct physical demands upon compromised joints.

Features of Osteoarthritis

Various biomechanical stressors operate in rheumatic disorders, to cause either aggravated symptomatology or accelerated tissue damage. Osteoarthritis (OA) and ankylosing spondylitis (AS) are diseases, which result in damage and deformity to peripheral or spinal joints. The mechanisms are believed to be primarily

caused by biomechanical stressors, at least in their initial stages. Later phases of these diseases may include some degrees of inflammation, either localized articular (OA) or combined joint and systemic (AS), but to lesser degrees than in RA.

Structurally, the basic elements of body design are balanced systems of compression and tension in its functioning components. Biomechanical stresses which alter such balance, e.g., excessive compression (chronic overloading from obesity) or excessive tension (suspected axial myofascial hypertonicity in AS) can contribute to accelerated joint damage or increased symptomatology.

In diarthrodial (freely moving) joints, movements occur across the smooth specialized cartilage tissue surfaces covering the ends of connecting bones (e.g., knuckles of the hands, hips, or knees). This remarkable cartilage tissue provides combined compressional elasticity (i.e., water trapping) and tensile strength (i.e., resistance to tearing). Although a popular lay concept is that joints are primarily designed to absorb impacts, their main function is to permit smooth movements in transmission of dynamic forces between connecting bones, ligaments, and muscles. Friction and impacting of joints are normally minimal, since surface movements (velocity vectors) are parallel to the joint contours, which have covering fluid films. The coefficient of friction across normally articulating joint surfaces is miniscule (Figure 1).

Figure 1 Schema of normal versus osteoarthritis joint. Anatomical features of a normal diarthrodial joint are schematically shown. The cartilage is a specialized tissue which normally provides compressible elasticity and resistance to tearing in smooth joint movements. Muscles and ligaments are attached to the joint capsule and bones, providing essential dynamic support and transfers of forces. In osteoarthritis, cartilage undergoes loss of tissue and function and the articulating bones undergo gross alterations in contours as well as defects in microarchitecture. The synovial lining of the joint becomes secondarily inflamed from reactions to the cartilage breakdown products and increased strains of a biomechanically stressed joint. Synovial changes in osteoarthritis are less manifest than in rheumatoid arthritis, where inflammation is a primary pathological process in the joint.

When joints are chronically overimpacted or overloaded, as in OA, the cartilage tissues begin to fail. Cartilage loses its normal elasticity, proper opposing surface conformations, and tensile integrity. The later stages of OA are characterized by substantial losses of cartilage substance, deformities of bones and joints (Figure 1). The consequences are loss of mechanical joint efficiency, pain on movements, secondary muscle atrophy, and decreased dynamic support. Thus, chronically decompensated or unbalanced biomechanical stresses can contribute to joint damage and later failure. Gross trauma can cause acute injury and loss of joint integrity, leading to subsequent chronic joint failure, as described above.

Features of Ankylosing Spondylitis

In AS, lesions usually begin in the sacroiliac joints (SIJs) or the lumbosacral vertebrae, at the base of the spine, where the truncal compressional forces are greatest (Figure 2). These joints have minimal, but essential, normal degrees of motion. They are primarily designed to provide stability as well as transfer of forces between the trunk and lower extremities and vice versa. The vertebral lesions in AS are mainly localized at the attachment tissues (enthesopathy), which result in secondary calcifications and immobilization by bony fusion of the connecting vertebrae. Typically, the spinal lesions progress from the base to higher levels, as limitations in movements and fixation occur below. In the SIJs, the pathological lesions progress from initial cartilage narrowing, to localized erosions of this tissue, and to final total cartilage loss, with obliteration of the joints by an intra-articular bony fusion process.

Figure 2 Skeletal structures relevant to ankylosing spondylitis. Skeletal structures of the lower vertebral spine, sacrum, and pelvis are shown. In ankylosing spondylitis, pathological changes typically occur first in the sacroiliac joints and the lumbosacral spine, which bear the greatest truncal loads. Biomechanical stresses are believed to play a major role in development and localization of tissue changes in this disease (see text).

Altered biomechanics is suspected to be important, if not primary, in the physiopathological processes in AS. One concept favored by these authors is that the SIJ lesions develop in a setting of excessive compressional forces across these joints, whereas the vertebral lesions result from excessive tensional stresses on the attachment tissues. In contrast, the popular concept is that inflammation is the primary mechanism at these sites. However, neither the initiating mechanisms nor explanation for the specific tissue localizations are elucidated in this inflammatory theory. If the above-mentioned biomechanical alterations are the main predisposing factors in AS, secondary inflammatory mechanisms could logically occur following chronic microinjury.

All organisms on this planet have evolved and adapted appropriately to resist forces of gravity. Accordingly, all normal tissues and body parts must possess sufficient cellular and structural integrity to resist gravity as well as to maintain an appropriate balance of stability and flexibility mechanisms to perform the vast spectrum of life's daily activities. Structural integrity of the musculoskeletal system is required at micro- and macroanatomical levels. Also, efficient biomechanical connectivity of the myofascial and osteoligamentous tissues is essential. Efficient transfers of physical energies and forces requires dynamically normal organization in the performance of the multitude of body movements and resistance activities. Compromised integrity of either the musculoskeletal structures or their dynamic organization predisposes to particular diseases like OA and AS as well as to accelerated joint damage in RA and other rheumatic conditions.

Possible Stressor Specificities to Particular Pathways

In order to better interpret how stressors can affect particular rheumatic disorders, it is important to understand the main mechanisms or systems alterations, which determine these respective conditions. For example, CNS pathways are believed to be the main mechanisms operating in FMS. They include enhanced emotional and sensory perceptual activation via autonomic and cognitive systems, rather than by alternative inflammatory or biomechanical stress mechanisms. Instead, dysregulations or activations of the NEI and MVE systems are believed to be the primary pathways in RA, leading to enhanced immunological and inflammatory reactivity. Whereas, biomechanical stressors are believed to cause the primary structural and tissue lesions in OA and AS.

Types of stressors that typically aggravate a particular rheumatic disorder may be related to the host's susceptibility to the respective condition. Stressor specificity

relationships to rheumatic disorders might be metaphorically described as a particular glove fitting the owner's hand, at least in part. If stress-disorder specificity does occur, the phenomenon may reflect a potential biological band-width resonance between the stressors and reactor systems (as suggested by Dr. Richard Imrich). Future investigations may permit a partitioning of stresses and their reactive effects according to degrees of stressor intensity and frequency and categories, in relation to the host's adaptabilities versus vulnerabilities, under particular environmental and psychosocial circumstances. For example, experimental and human data suggest that repeated stress exposures under controlled and supportive conditions tend to increase resistance to adverse reactions (favorable conditioning) and vice versa (enhanced vulnerability).

Although certain stressors tend to primarily aggravate one or another rheumatic disease pathway, they can often indirectly or secondarily affect other disease systems. Thus, particular types of stressors are common in related rheumatic disorders, but they are not strictly compartmentalized in their effects. Stressors can have varied degrees of overlapping primary or secondary influences due to complex interactions of the host and environmental circumstances in a particular disorder.

An extensive spectrum of psychological, systemic, physical, or biomechanical loading factors can influence rheumatic disorders. Each condition tends to have its respective pattern of host susceptibilities, somatic developmental influences, psychosocial predispositions, or correlated behaviors. The different disorders show relative reactivity to the varied environmental stimuli, stresses, or challenges. Individuals differ in multiple and complex ways, and are affected differently by the respective heterogeneous stressors. Therefore, only general interpretations can be made regarding the main types of stressors affecting particular rheumatic disorders, and considerably more research is needed in this area.

Profoundly Complex Patterns of Stress Responses

Central Stress Systems

Different stressors of sufficient intensity can elicit relatively patterned responses via multiple effectors. The intensity of stressors and their consequent responses may be either relatively limited or more greatly enhanced. Limited psychophysiological stresses may primarily stimulate CNS and ANS pathways. Enhanced systemic stressors may also significantly activate the hypothalamic-pituitary-adrenal (HPA) axis and related neuroendocrine effectors. These include the two adrenal systems, i.e., the adrenocortical

(corticosteroids) and the adrenomedullary (adrenaline). Other HPA axis components contribute to stress-related responses, which are intended to diminish acute tissue injuries and modulate overstimulation of the immunological and inflammatory responses.

Neurodynamic models of the brain propose that sensory circuits can be tuned, for purposes of selectively sensitizing the cortices to desired or expected inputs. Such dynamics enhance selective attention and intentional learning. However, selective sensitivity and central sensitization in people susceptible to FMS and related conditions could possibly overamplify signals perceived to be aversive. In overly distressed people, such mechanisms would need to be modulated or unlearned, in order to relieve sensory and psychic pain induced by stressful psychosocial stimuli.

Although ANS dysfunction may explain many of the multisystem features of FMS, a fundamental dilemma is whether such activated status is constitutionally predisposed or developmentally acquired. Some data indicate that HPA or ANS dysfunctions may be acquired responses in particular people (possibly innately susceptible) who are exposed to various stressful psychosocial or other life circumstances, particularly during childhood or developmental stages. Carefully controlled prospective studies in family settings will be needed to better assess the dynamic impacts of stress mechanisms on familial versus environmental backgrounds, and their interactions. Such data can clarify the respective roles of these components in FMS, related disorders, and symptomatic patterns of illnesses generally.

Responses to major emotional or physical stresses are physiologically integrated by the HPA axis, the adrenal medulla, and the sympathetic nervous system (SNS). People differ in their susceptibility to physical stresses or psychoneuroendocrine perturbations. Some people have limited versus robust stress reactions, depending upon the integrity of their physiological adaptation. Healthy, well-conditioned, younger people generally react more favorably to systemic stresses (i.e., less allostatic load), than elderly or frail individuals, who may more likely show adverse reactions and consequences.

Variability in Central Nervous System Stress Responses

Individuals vary in cognitive or perceptual sensory sensitization and in their SNS activation, due to genetic, developmental, and psychosocial or behavioral conditioning. Stresses that perturb these CNS pathways can amplify many subjective complaints by central sensitizing mechanisms. Such symptoms include greater intensity and distribution of pain, anxiety, or dysphoria, increased arousal and nonrestorative

sleep, easy fatigue, and generally diminished functional ability. More limited intensities of psychosocial, physical, and environmental stresses may not be sufficient to perturb the majority of individuals in the population, nor be significant factors to predictably alter NEI-MVE interactions in the majority of people. However, people more susceptible to the preceding limited stressors (i.e., those having low stress tolerance) may nevertheless experience significantly enhanced symptomatology or dysfunctions.

In FMS patients, stress susceptibility pathways seem to be related mainly to increased central sensory sensitization mechanisms. Such pathways can enhance perceptual pain and autonomic emotive reactions, but not necessarily affect systemic neuroendocrine or immune mechanisms that predispose to inflammation. Susceptibilities to particular rheumatic disorders seem to be amplified by complementary stressors. In FMS, the more evident stressors seem to primarily impact central sensitization pathways. However, various stressors can secondarily influence sleep and physical conditioning, and can affect other body systems. In addition, emotional or biomechanical factors can also amplify symptomatology in FMS and related disorders.

Stress Reactivity and Systemic Pathways

In subsets of RA patients, stressors are believed to impact the HPA axis and MVE pathways. These systems may possibly show greater stress responsiveness in RA patients due to: (1) innate deficiencies in counterregulatory competence; (2) behavioral exposures or constitutional susceptibility to endothelial microvascular activation, or (3) constitutionally increased immunological or inflammatory activation, which are described further below.

Biomechanical Stresses and Anatomical Structures

Although, OA and AS are strongly affected by biomechanical stresses and gravitational forces, other rheumatic conditions can also be influenced by such factors. In the spinal column, vertebral bodies act mainly as compressional and supportive members, whereas the intervertebral anterior longitudinal ligament acts as a binding or tensional element. In the spine, forces are transmitted at specialized junctional sites, where spinal ligaments attach to the vertebral bodies (i.e., entheses). Such anatomical design allows both stability and mobility via the shared functions of the compressional and tensional osteoligamentous elements. However, such passive osteoligamentous structures alone do not permit sufficient stability to maintain anatomical equilibrium against gravitational forces, let alone provide for stabilized movements

or resistance activities. It is the skeletal and particularly postural muscles that provide the requisite supportive and movement functions in the body via their active contractile mechanisms and mechanical tone.

Complex Integrated Homeostasis and Stress Responses

Complex net interactions occur among the different homeostatic systems and subsystems. In physiological balance, prompt compensation occurs among the systems in response to varied changes. A primary versus secondary perturbation is difficult to distinguish, unless the pathways are known to be predetermined. In chronic disease, e.g., RA, dysregulations in the NEI and MVE systems occur concurrently. Their sequences of perturbations are not known and cannot be determined in cross-sectional analyses. The respective sequential changes must be analyzed over the course of time in prospective studies. Such longitudinal studies can better differentiate initial or primary alterations from secondary pathways, and are a priority objective for future research. Integrative longitudinal analyses offer greater promise to uncover complex mechanisms in chronic diseases with multifactorial determinants, than reductionist analyses which mainly address single-factor pathogenic mechanisms.

Stressors Related to the Physiopathogenesis of Rheumatoid Arthritis

The major example of a rheumatic disorder in this article is RA. It illustrates important principles pertaining to the group of systemic inflammatory diseases and how they may be influenced by various stressors. Considering only the adult onsets of RA in this discussion, the clinical spectrum is decidedly heterogeneous in patterns of manifestations and in degrees of severity. Such disease heterogeneity (phenotypes) may be attributable to a combination of innate genetic predispositions, somatic developmental influences as well as interactions with environmental factors and their respective stressors.

Primary versus Secondary Stress Pathways in RA

A fundamental objective in clinical research is to differentiate primary determinant factors from secondary reactions in the development and course of disease. Both the presymptomatic and clinically active phases of disease need to be critically investigated. Additionally, a priority challenge is to determine normal relations and interactions among the relevant physiological systems in health that become altered in the disease process. Generally, little research

Figure 3 Balance of rheumatoid arthritis determinant factors. The recognized precursor risk factors and counteropposing protective factors for onset of rheumatoid arthritis are schematically shown. Normally, counterregulation occurs between activation of the immunological and microvascular endothelial systems and the anti-inflammatory systems, including glucocorticoids, androgens, and sympathetic nervous system (SNS) mediators. In RA, heavy cigarette smoking and other stressors are believed to dysregulate normal physiological balance and enhance activation of inflammatory pathways (see text).

data are available on such early physiological interactions in clinically healthy subjects or in susceptible people before clinical onset. Most available data pertain to the pathological alterations that occur during active phases of clinical disease, without knowing the physiopathogenetic pathways (Figure 3).

Stressors may Amplify Dysregulations in RA

Under normal circumstances, counterregulatory balance occurs between the NEI systems. Once disease manifests, definite immunological activation and inflammation become evident, which, in turn, stimulate the HPA axis. In active disease, blood levels of the main inflammatory cytokines are significantly elevated (i.e., interleukin (IL)-1 β , IL-6, and tumor necrosis factor (TNF)- α), and they centrally stimulate the HPA axis. The HPA axis products normally act to counter-regulate overactivation of inflammatory pathways (Figure 3). However, such HPA axis actions are suspected to be relatively deficient in some people susceptible to RA, particularly younger women with onsets in their premenopausal ages.

In humans, cortisol is secreted from the adrenal cortex as the main anti-inflammatory product of the HPA axis, whereas in rodents, corticosterone is the main glucocorticoid. Blood levels of these corticosteroids are tightly controlled by negative feedback

mechanisms at the hypothalamic and pituitary (HP) levels. The concept has evolved that relative deficiency or insufficiency of glucocorticoid responsiveness permits inappropriately exaggerated activation of the immunological and microvascular endothelial systems. Increased predisposition to inflammatory disorders may also result from natural susceptibilities via other host immunological mechanisms or added predispositions from varied stressors.

Firm data are not available on mechanisms or pathways whereby particular stressors can alter the normal psychoneuroendocrine physiology and influence susceptibility to RA. However, one study of 2490 Vietnam Theater Veterans diagnosed as having PTSD showed a fivefold increased likelihood to have postwar RA. That study and other data may indicate that people with relatively lower HPA axis and SNS stress responsiveness may be more susceptible to both PTSD and autoimmune disorders, like RA. Alternatively, stressors that predispose to PTSD may suppress HPA axis responsiveness via inhibition of corticotropin-releasing hormone (CRH). In turn, counterregulation of immunological activation could be diminished. Research on presymptomatic risk factors for onset of RA indicate that increased predisposition is related to evidences of: (1) increased immunological activation, (2) physiologically lower adrenal cortical reserve in younger women, and (3) history of heavy cigarette smoking in females and males, all of which may impact stress responsiveness of the NEI and MVE systems.

An Evolving Research Challenge in Rheumatoid Arthritis

In growth, maturation, and later aging into the senescent period, marked changes normally occur in the NEI and MVE systems. Attempts have been made to correlate such important physiological changes with risks of developing RA in the population. In women, incident risks of RA onset increase rather regularly with aging, from adolescence to the people in their seventies. However, in males aged 15–50 years, the risks are level and low, about one-fifth as high as in females. Such differential susceptibility patterns indicate that males are relatively protected during their younger adult and more masculine years. From such data, adrenal and gonadal androgens have been implicated as being protective of RA, perhaps by exerting greater control of immunological activation.

Estrogens control endothelial cell activation more effectively than androgens. Premenopausal women have significantly lower natural risk of coronary artery disease (CAD) and myocardial infarction (MI) than male counterparts. Sufficient intensity and duration of cigarette smoking exposures are stressful

vasculotoxins that increase risks of CAD and RA in both sexes. The smoking effect on CAD is magnified in women by use of oral contraceptives (OCs), which provide supraphysiological or pharmacological doses of estrogens. However, OCs alone have not been proven to amplify risks of RA. Also, pregnancy typically improves RA activity, which argues against female sex hormones being a primary risk factor.

Pharmacological doses of estrogens have been shown to increase risks of CAD and MI in both females and males. However, the mechanism is likely to be due to increased thrombogenic risks, rather than by microvascular endothelial or inflammatory pathways. Interpretation of such clinical-epidemiological risk patterns are difficult. Nevertheless, tentative hypotheses may be drawn.

First, heavy cigarette smoking is a stressor which increases risks for a large spectrum of microvascular-related disorders, including RA, and equally so in males and females.

Second, males have significantly lower natural risk of RA during their younger adult ages, suggesting greater control of immunoactivation during those years of highest androgenicity. A significant association of PTSD and RA is reported in Vietnam Theater Veterans, suggesting that stress or diminished tolerance thereto may be a susceptibility factor. Typically, stress reactions result in decreased androgen levels, which could affect susceptibility to RA in males.

Third, estrogen levels *per se* are not correlated with increased RA risks, because younger and pregnant women have considerably lower incidence than postmenopausal women. Also, OCs have not been proven to increase RA risk. Thrombogenic pathways, enhanced by pharmacological doses of estrogens, do not seem to be a primary mechanism in RA, in contrast to immunoactivation and MVE perturbations.

Summary

Interfaces of the immunological and microvascular endothelial systems seem to be primarily incriminated in the inflammatory pathways in RA. Their activation may be amplified permissively by relatively insufficient HPA axis counterregulatory controls. Sufficient cortisol responsiveness is needed to control capillary permeability and transmigration of inflammatory cells into the interstitium. This potent hormone is also required to control overactivation of the immunological system and inflammatory cytokine production, which are key mediators in the RA process.

Stressors and environmental activators may be suspected as being contributory co-factors in the complex web of causation of RA (Figure 3). Heavy cigarette smoking has known microvascular toxic effects. Also, stressful life circumstances likely compromise

normal HPA axis counterregulatory control functions and diminish androgen levels, particularly in males. The glucocorticoids, cortisol in humans and corticosterone in rodents, are the most potent anti-inflammatory products of the HPA system and in the stress response. However, many additional steroid hormones are secreted by the adrenal cortex, in addition to those products of the gonads. Also, catecholamines are secreted by the adrenal medulla and ANS, which are normally immunosuppressive. Besides glucocorticoids, these additional products of the HPA axis, gonads, and ANS can also modulate activation of the immunological–endothelial systems and control their interactions. Further research is needed on the complex relations of stress reactions to risks and course of RA and other rheumatic disorders.

Methodological Issues

Salivary Cortisol Stress Responses

Field Studies and Ambulatory Assessments

Psychoendocrine Stress Research in Infants and Children

The hypothalamic-pituitary-adrenal (HPA) axis responds rapidly and rather specifically to a wide range of environmental and internal demands often referred to as stress. It is thought that the HPA response to stress plays a pivotal role in the organism's attempt to maintain function through change, as expressed in the allostasis model. Although the HPA hormones corticotropin releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH) may exert additional adaptive effects, accumulating evidence suggests that cortisol is the main hormone responsible for allostatic stress responses.

Following stimulation by ACTH, cortisol is synthesized and secreted from the adrenal glands and released into the circulating blood, where it is bound rapidly to carriers such as corticosteroid-binding globulin (CBG), albumin, and erythrocytes. Only a small fraction (2–15%) of cortisol released remains unbound, or free. According to the free hormone concept, it is only this hormone fraction that brings about the multitude of genomic cortisol effects in peripheral tissues and in the brain. Although in blood both bound and free cortisol can be measured, only free cortisol appears in saliva. Hence, the measurement of salivary cortisol provides an index of the biologically active fraction of this steroid hormone.

Methodological Issues

For decades, research on the acute and chronic effects of stress has employed cortisol levels as an index of the individual response to stress. Due to methodological reasons, this research was slowed by the need for multiple blood samples to measure cortisol levels repeatedly. Blood sampling is not only labor-intensive (and expensive) but sometimes also counterproductive in stress research because the procedure of venipuncture itself can lead to significant HPA activation. The advent of advanced biochemical assays capable of measuring cortisol reliably in the lower nanomolar range, however, helped to overcome this problem.

Since the mid-1980s, the assessment of free cortisol in saliva has become an increasingly important tool in stress research because it has a number of advantages over the measurement of cortisol in blood or urine. Of prime interest to the stress researcher is the noninvasiveness of sampling and the ability to obtain samples at short intervals from subjects over the entire life span without raising ethical problems associated with venipuncture. The measurement of cortisol levels in saliva is the method of choice for field studies or ambulatory assessments in the natural environment of the subjects because medical personnel or laboratory facilities are not required for collecting and storing the samples. Salivary cortisol is not measured only in humans, it also serves as an endocrine correlate of stress in animals, including pigs, monkeys, elephants, sheep, tree shrews, guinea pigs, and goats.

Sampling, Storage, and Biochemical Analysis

Samples are usually obtained by the subjects or patients; infants and young children (<2 years old) require additional help from parents or hospital staff. Subjects either salivate directly into small containers or use devices such as the Salivette, which is currently the most frequently employed sampling method.

Stimulation of saliva flow by gently chewing on the device or by adding a few crystals of sugar-sweetened Kool-Aid (for use with infants and small children) ensures adequate sample volume. Because most immunoassays available today provide false high values with low pH samples, saliva should not be sampled after stimulation with citric acid. The storage and mailing of samples are uncomplicated. Because cortisol is rather stable in saliva, samples can be stored at room temperature for at least 4 weeks without a significant reduction in cortisol concentration or mailed to a laboratory at ambient temperature, even overseas. However, in order to keep samples over prolonged periods and to avoid molding, it is recommended that samples be stored at -20°C or lower. For the biochemical analysis of salivary cortisol, several methods are now available that allow reliable measurement of the steroid hormone. Immunoassays with radioactive and other tracers are the method of choice for most laboratories. An increasing number of commercial assay kits designed for use with serum or plasma now also provide instructions for use with saliva. In a few instances, the use of alternative analytical techniques may be required. For example, the simultaneous detection of several steroid hormones and their metabolites in saliva can be achieved with high-pressure liquid chromatography (HPLC). Also, for processing samples that contain high levels of compounds (e.g., prednisone) that cross-react significantly with most antibodies raised against cortisol for use with immunoassays, HPLC may be the adequate analytical technology. Gas chromatography-mass spectrometry is used only for validating cortisol results obtained with other assay methods.

Comparison with Cortisol Levels in Blood

Because cortisol is a small (molecular weight, MW, 362) and highly lipid-soluble molecule, the unbound hormone can pass easily through the lipid-bilayer membranes of nucleated cells. This allows free cortisol to appear in all bodily fluids, including blood, cerebral spinal fluid, urine, sweat, semen, and saliva. Cortisol bound to carriers is usually excluded from these body compartments.

Most important for stress research, cortisol levels measured in saliva agree very well with the amount of free cortisol in blood. Correlations between salivary and unbound blood cortisol levels usually explain more than 80% of the total variance observed ($r \geq 0.90$). This high agreement is due to the fact that cortisol enters the cell and the oral cavity mainly by passive diffusion. It is therefore independent of transport mechanisms and saliva flow rate, in contrast to other components also found in saliva

(e.g., immunoglobulin A and catecholamines). Absolute levels of free cortisol are lower in saliva due to a relative abundance of the cortisol-metabolizing enzyme 11- β hydroxysteroid dehydrogenase.

Circadian Rhythm and Normal Values

As in blood, salivary cortisol levels follow a robust circadian rhythm that has been studied only in awake subjects so far. Peak levels are usually found in the early morning hours, with decreasing values thereafter. Several secretory episodes can be detected throughout the day, even in the absence of psychological or physical stress.

Stimulated by an individual's waking up in the morning, there is a 50–100% increase in cortisol levels, peaking about 30 min after awakening. This response shows remarkable stability over weeks and months in the same individual and has been found to relate to prolonged stress exposure and the feeling of burnout. After the morning peak, cortisol levels decrease steadily until a second major secretory episode occurs in response to larger meals at lunch time. As with the wakening response, meal-related peaks appear to be more pronounced (approximately 1.5-fold) in free cortisol compared to total blood cortisol. During afternoon and evening hours, saliva cortisol continues to decrease with no further major secretory episode. [Figure 1](#) depicts the circadian rhythm of cortisol in saliva representing normal values typically observed in a healthy population.

Figure 1 Normal values of salivary cortisol during the day (white line: mean levels; shaded area: means ± 1 SD).

Salivary Cortisol Stress Responses

Response Kinetic

In contrast to other neuronal and endocrine response circuits, it takes several minutes before an HPA stress response becomes visible in the periphery. After the onset of a psychosocial stressor or strenuous exercise, ACTH levels start to rise within less than 5 min and show peak values shortly after the cessation of stress (<5 min). The cortisol response lags by 5–20 min, with maximal cortisol levels 10–30 min after stress cessation. Although cortisol exerts a strong feedback action at the level of the pituitary, hypothalamus, and hippocampus, prolonged periods of stress can lead to cortisol secretion over several hours. For example, in marathon runners, salivary cortisol was observed to increase monophasically for more than 4 h, peaking approximately 30 min after the run was finished.

The transfer of cortisol from plasma to saliva occurs quickly. Within less than a minute, cortisol injected intravenously appears in saliva, and the peak concentration in saliva lags by less than 2–3 min compared to levels measured in blood. Thus, it is not surprising to find similar stress response kinetics in saliva and in blood. For example, total plasma cortisol and salivary cortisol levels rise in parallel in response to a laboratory stress task that consists mainly of an anticipation period (3 min), public speaking (5 min), and mental arithmetic (5 min) in front of an audience. Following the cessation of stress, however, free cortisol tends to increase further for another 15–20 min, whereas total cortisol levels

are unchanged or start to decline (Figure 2). A similar response pattern was observed in plasma after meals, bicycle ergometry, and injection of ACTH(1–24) and during sleep.

Discrepancy between Salivary Cortisol and Total Plasma Stress Responses

Although salivary cortisol levels agree well with plasma-free cortisol, they show only moderate correlations with total cortisol levels under certain circumstances. Although the adrenal cortex was stimulated by ACTH and secreted significant amounts of cortisol, subjects may show blunted or completely absent cortisol responses as measured in saliva. This phenomenon can be observed in women using oral contraceptives (OC) (Figure 3). The use of oral contraceptives leads to an increase in CBG levels and hence to a larger number of binding sites for cortisol in the circulating blood. Therefore, more cortisol released from the adrenals is bound by CBG in these women than in non-OC users, and lower levels of the biologically active free fraction appear in saliva (as well as in target tissues). Similar discrepancies between total blood and salivary cortisol levels should be expected in all cases of increased or decreased CBG production.

Field Studies and Ambulatory Assessments

One of the major advantages of salivary cortisol is that samples can be obtained in the field, that is, in the natural (social) environment of the subjects/patients

Figure 2 Mean ACTH, total plasma cortisol, and salivary cortisol responses to a brief psychosocial stress test (Trier social stress test). Note that there are different units of hormone concentrations for total plasma and salivary cortisol.

Figure 3 Cortisol responses to stress in women using oral contraceptives (OC) and nonusers. a, Salivary cortisol levels; b, Total plasma cortisol and corticosteroid-binding globulin (CGB) levels. The blunted free cortisol response pattern in OC users is not due to lower cortisol secretion but rather a consequence of enhanced CGB levels. AUC, area under the curve.

as well as in special settings outside a psychological or medical laboratory. This advantage has allowed researchers to perform a number of studies that would have been very difficult or even impossible with blood sampling. With saliva, large cross-sectional studies can be performed by mailing sampling devices and instructions to the subjects, who return the material by regular mail to the laboratory. Populations of 500–1000 subjects or more can be investigated easily by this method.

Of special interest to the stress researcher is the ease of obtaining cortisol readings from subjects repeatedly before and after exposure to real-life stress situations. For example, the impact of the first three parachute jumps on acute HPA responses and subsequent pharmacological tests was studied with saliva samples obtained at the airfield at 20-min intervals over 10 h. In addition, the same subjects collected saliva samples at identical times on a control day to relate the stress-induced changes to the individuals' normal circadian rhythms. Furthermore, ambulatory (or momentary) assessments of cortisol responses to daily stress can be performed independently of the researcher. Using electronic devices such as preprogrammed wristwatches and pocket-size (computer) booklets, researchers can beep study subjects several times a day and request a report on current, past, or anticipated stressors. Twenty minutes later, they beep the subjects again and ask them to take a saliva sample. Several studies with momentary assessments of stress and salivary cortisol have been published supporting the view that even minor

changes in negative affect can result in increased cortisol levels, whereas a positive affect has the opposite effect.

Psychoendocrine Stress Research in Infants and Children

For ethical reasons, invasive measures are usually prohibited for use with healthy infants or children. Circumventing these difficulties, the availability of salivary cortisol has stimulated research into the psychoendocrinology of stress in infants and children significantly. A rapidly growing literature shows that the human HPA axis begins to respond to psychosocial or physical stimulation with an activation of the axis very early in life. In combination with appropriately modified protocols, the acute response to experimental stress can thus be monitored in children and compared directly with adult response patterns, which will eventually lead to a more detailed understanding of the ontogenesis of the human HPA stress response.

Introduction

Environmental Stress and Salt (Sodium Chloride) Appetite

Hormones of the Hypothalamic-Pituitary-Adrenal Axis

Associated with Stress and Salt Appetite

Brain Mechanisms Involved in Stress-Induced Salt Appetite

Conclusion

Glossary

<i>Homeostasis</i>	The maintenance of a relatively constant internal environment.
<i>Hypertension</i>	Abnormally or excessively high blood (arterial) pressure.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The integrated association between the hypothalamus (an area of the brain that integrates the various automatic body reactions), the pituitary gland (a small gland at the base of the brain that controls hormone release from the adrenal gland), and the adrenal gland.
<i>Ingestive behavior</i>	Taking food or fluid into the body as nourishment.
<i>Lesion</i>	The removal of or irrevocable damage to a localized region of body tissue.

Sympathetic nervous system

One of the two divisions of the autonomic nervous system. It innervates involuntary processes, which are largely beneath consciousness (e.g., the actions of the visceral organs, heart, blood vessels, glands, and smooth muscle). The activation of the sympathetic nervous system prepares the body for fight or flight and works antagonistically with the second autonomic division, the parasympathetic nervous system.

Introduction

Stress is often seen as a major contributor to disease, with specific effects on several of the body's physiological and behavioral systems. Its effect on the cardiovascular system may result in increased mortality. In addition, stress or the hormonal consequences of stress cause several changes in ingestive behavior. Evidence suggests that stress or the hormones of stress can directly influence the intake of salt (sodium chloride). An increased intake of salt is widely accepted to be a factor in the causation of hypertension and, in some instances, it magnifies the cardiovascular effects of stress. Evidence regarding the brain mechanisms involved in the changes in salt appetite caused by stress and the hormones of stress are described.

Environmental Stress and Salt (Sodium Chloride) Appetite

Environmental stress can result in increased salt appetite, as has been shown in several ways. One of the first demonstrations was made while attempting to fit jackets, designed for carrying small infusion pumps, on wild rabbits (see [Figure 1](#)). This minor restraint on free movement caused the rabbits to become agitated, and, over the course of several days, a spectacular increase in salt appetite was observed – their intake of a concentrated salt solution increased by over 15-fold. This intake of salt approximated a daily turnover of 30% of extracellular fluid sodium, sodium in the tissue fluid outside the cells. In similar experiments in which restraints were placed on mice (see [Figure 2](#)), an increase in salt intake was also observed. This salt intake was eliminated by the subcutaneous administration of the drug captopril; this drug prevents the formation of the peptide hormone angiotensin II. Angiotensin II, produced peripherally (i.e., in the circulation) and in the brain, is involved in both sodium and cardiovascular homeostasis, and it is one of the hormones known to be elevated in stressful situations. Increased levels of angiotensin II are

Figure 1 Jack Nelson holding a wild rabbit in a jacket designed to carry infusion pumps.

Figure 2 Restrained mouse on running wheel.

also thought to explain the increased salt intake of mice kept in a cold environment for several hours a day. It is well known that rats from one colony become over-reactive when introduced into another colony. An increased salt appetite has been documented in these stressed animals.

The sympathetic nervous system is responsible for the fight or flight response in animals confronted with stressful situations. Drugs such as clonidine or reserpine, which interfere with the actions of the sympathetic nervous system, block the characteristic stress-induced increase in salt intake. This suggests that the increase in salt intake involves the increased activity of the sympathetic nervous system.

Figure 3 Two adult male Sprague-Dawley rats in conflict during crowding.

Crowding, an imposed social stress, was also found to increase salt intake in rats. Following a control period during which rats were housed alone in a small individual cage, two rats were placed together into a different cage (see [Figure 3](#)). The intake of concentrated salt solution increased over several weeks.

In summary, animals maintained in stressful situations have been shown to manifest an increase in salt intake. This increased salt intake is mediated by increased levels of the hormones associated with stress, namely, the hormones of the hypothalamic-pituitary-adrenal (HPA) axis, primarily adrenocorticotrophic hormone (ACTH) and the mineralocorticoid/glucocorticoid hormones secreted by the adrenal gland. Angiotensin II, another hormone whose levels are increased in stressful situations, can stimulate the secretion of ACTH and the adrenal hormones. Interfering with the actions of angiotensin II can block salt appetite induced by stress. At present, the contribution of the sympathetic nervous system to salt appetite induced by stress seems paradoxical given that the activation of this system causes increased blood pressure.

Hormones of the Hypothalamic-Pituitary-Adrenal Axis Associated with Stress and Salt Appetite

It is well documented that hormones of the HPA axis (see [Figure 4](#)) can cause salt appetite. These include corticotropin releasing hormone (CRH) from the paraventricular nucleus of the hypothalamus, ACTH from the pituitary gland at the base of the brain, and the adrenocortical hormones (often referred to as steroid hormones), including the mineralocorticoid hormones, aldosterone and deoxycorticosterone and the glucocorticoid hormones, corticosterone and cortisol. The name of the former suggests their

important role in the retention of minerals (i.e., salt) in the body and the name of the latter reflects their role in glucose metabolism. CRH and the more recently discovered urocortin (UCN) are thought to have a major physiological role in the response to stress, including the stimulation of ACTH secretion. ACTH and angiotensin II are important in stimulating the release of the mineralocorticoid hormones from the adrenal cortex.

Adrenocortical Hormones

There are at least 20 known steroid hormones with numerous functions as well as catecholamines produced and secreted by the adrenal gland. Work, started over 50 years ago, has demonstrated that the administration of mineralocorticoid hormones (aldosterone or deoxycorticosterone) causes salt appetite. Mineralocorticoid-induced salt appetite has been shown in rats, mice, rabbits, hamsters, and sheep. Sheep treated with deoxycorticosterone shift their preference from a low-salt diet to a high-salt diet, and the increased intake of salty food is associated with an increase in both water intake and blood pressure. In addition, infusion of aldosterone into the brain causes increased blood pressure in rats.

Mineralocorticoid hormones may also influence salt appetite in the rat by its interaction with angiotensin II. The synergy between the mineralocorticoid hormones and angiotensin II may be due to the ability of the mineralocorticoid hormones to increase the number or sensitivity of angiotensin II receptors. Evidence contrary to the proposal that salt appetite is caused by a synergy between mineralocorticoids and brain angiotensin II has been reported in sheep. Data regarding the synergy hypothesis are inconclusive in the pigeon and rabbit.

The administration of either cortisol or corticosterone increased salt appetite in rabbits and mice. The concurrent administration of both cortisol and corticosterone increased appetite by more than the sum of the individual intakes. This result suggests a synergy between the two glucocorticoid hormones. In humans, the administration of cortisol increased blood pressure but did not alter salt preference.

The glucocorticoid hormones may contribute to salt appetite by potentiating the appetite caused by mineralocorticoid treatment. The administration of corticosterone or dexamethasone, a potent synthetic glucocorticoid hormone, for example, enhances salt appetite induced by aldosterone or deoxycorticosterone in rats. A similar influence has been reported in mice.

In experiments in sheep, the intravenous infusion of a combination of steroids, a treatment that mimics

Figure 4 Some of the mechanisms affecting salt appetite and blood pressure. ACTH, adrenocorticotrophic hormone; AMYG, amygdala (a laterally situated structure shown in central perspective); Ang II, angiotensin II; BNST, bed nucleus of the stria terminalis; CRH, corticotropin releasing hormone; OVLT, organum vasculosum of the lamina terminalis; PVN, paraventricular nucleus of the hypothalamus; SFO, subfornical organ; SNS, sympathetic nervous system; UCN, urocortin.

the effects of ACTH administration, increased salt appetite by an amount similar to that observed in sheep treated with ACTH. Blood pressure was also increased. The steroids infused included both mineralocorticoid (aldosterone and deoxycorticosterone) and glucocorticoid (corticosterone, cortisol, and 11-deoxycortisol) hormones and produced blood levels of these hormones similar to those observed during ACTH administration. Blood pressure was also elevated in this instance. However, the infusion of the steroids into the arterial blood directly supplying the brain or directly into the brain did not increase blood pressure. This suggests that, in contrast to the influence of aldosterone on blood pressure in the rat,

the steroid-induced increase in blood pressure in sheep is not due to a central effect of the steroids.

In summary, an increased intake of salt is produced by the administration of mineralocorticoid and/or glucocorticoid hormones. Several synergies between adrenal hormones in regard to the stimulation of salt appetite have been reported. Also, mineralocorticoid hormones may work in conjunction with angiotensin II to stimulate salt intake.

Adrenocorticotrophic Hormone

ACTH was isolated from mammalian hypothalamus in the 1940s–1960s; it has the following properties:

- It is a 39-amino-acid peptide, derived from pro-opiomelanocortin and found primarily in the pituitary gland but also found in the brain (e.g., the arcuate nucleus).
- Its levels are elevated during stress.
- It controls the adrenal corticosteroid responses to stress.

The administration of ACTH causes a large increase in salt intake in several species such as sheep, rabbits, rats, and mice. When rats were offered a choice among concentrated solutions of sodium chloride, potassium chloride, calcium chloride, and magnesium chloride, their appetite was primarily for the sodium chloride solution. The intake of water was also increased. By the fifth day of treatment, the salt intake (and output) was equivalent to the daily turnover of total body salt. In mice, the increase in salt intake caused by ACTH was not altered by treatment with captopril. The observation that the stress-induced (but not ACTH-induced) salt intake was blocked by captopril suggests that the stress-induced production of angiotensin II precedes the increase in ACTH; that is, in stressful situations, angiotensin II has an important role in the stimulation of ACTH secretion.

Angiotensin II, administered into the circulation or directly into the brain, can stimulate the secretion of ACTH, possibly by stimulating the secretion of CRH from the paraventricular nucleus of the hypothalamus. The increase in water intake caused by ACTH has been shown to occur in rats and mice that were offered only water to drink. Results showed that ACTH caused an increase in the extracellular fluid sodium concentration, which caused the enhanced water intake. The administration of ACTH into the circulation causes a large and sustained increase in blood pressure in sheep, rats, and humans. In humans, blood pressure was elevated even when the dietary salt intake was low; however, much larger increases in blood pressure occurred when salt intake was high. In both sheep and rat studies, ACTH-induced increases in salt appetite and blood pressure were eliminated by adrenalectomy, suggesting that this mechanism is dependent on the adrenal hormones. In sheep, ACTH treatment also increased the heart rate.

Corticotropin Releasing Hormone and Urocortin

CRH was isolated from sheep hypothalamus and characterized in the early 1980s; it has the following properties:

- It is a 41-amino-acid peptide, primarily from the paraventricular nucleus of the hypothalamus but also found in other brain nuclei and in peripheral tissues.

- Its levels are elevated during stress.
- It coordinates responses to stress: increases the synthesis and release of ACTH from the anterior pituitary and influences the autonomic nervous system (e.g., increases sympathetic activity).
- Its actions are mediated by two receptor subtypes: CRH-R1, CRH-R2 (G-coupled, seven-transmembrane, bound receptors).

UCN was isolated from rat midbrain and characterized in 1990s; it has the following properties:

- It is a 40-amino-acid peptide, found in the brain (e.g., in the Edinger–Westphal nucleus, lateral superior olive, lateral hypothalamus, and supraoptic nucleus) and peripheral tissues (e.g., the pituitary, heart, and gastrointestinal tract).
- Its levels are elevated during stress.
- It coordinates responses to stress.
- Its actions are mediated primarily by CRH-R2 receptors.

CRH and UCN are found in brain areas known to be important for body sodium homeostasis (e.g., the hypothalamus; septal area; organum vasculosum of the lamina terminalis, OVLT; and amygdala) as well as in systems associated with autonomic function (e.g., the parabrachial nucleus and locus coeruleus). CRH and UCN are increased in the brain by stress and are involved in the initiation of the behavioral and physiological responses to stress. The major actions of CRH and UCN include the release of ACTH and the activation of the sympathetic nervous system. CRH also causes increased locomotor activity and modulation of the immune response. UCN shares a 45% homology with CRH, has CRH receptor-binding characteristics, and has a potency suggesting that it may mediate some of the actions, particularly of a behavioral nature, attributed to CRH.

The actions of CRH and UCN appear to be mediated by at least three CRH receptors ($-R1$, $-R2\alpha$, and $-R2\beta$) located in brain. CRH-R1 receptors are located in various regions of the cerebellum, several cortical areas, and the anterior and intermediate lobes of the pituitary. CRH-R2 receptors are located in the lateral septal nucleus, medial and cortical nuclei of the amygdala, bed nucleus of the stria terminalis, hippocampus, hypothalamic regions, and the serotonergic neurons of the midbrain raphe nuclei. CRH-R2 receptors are important in integrating hypothalamic neuroendocrine functions, as well as the autonomic and behavioral actions of central CRH. CRH-R2 α receptors are almost exclusively in the brain; CRH-R2 β receptors are found in brain and periphery. CRH-R2 receptors have a 6- to 40-fold greater affinity for UCN than for CRH.

The administration of ovine CRH in the brain of rabbits increased sodium intake, caused a sustained increase in both cortisol and corticosterone, and transiently increased blood pressure by 10 mmHg. The administration of CRH into the circulation did not influence salt intake. In recent experiments in sheep, however, prolonged central (see Figure 5) or peripheral (see Figure 6) administration of CRH or UCN failed to stimulate, and in fact inhibited, salt appetite despite stimulating the secretion of ACTH, as evidenced by the increased plasma levels of cortisol. Furthermore, the prolonged administration in the brain of CRH and UCN decreased food intake and need-free salt intake in sheep, rats, mice,

and baboons. The decrease in salt intake in baboons was transient, but the decrease in food intake was sustained throughout the infusion period. The mechanisms responsible for the inhibition of salt appetite are unclear. In sheep, the prolonged central or peripheral administration of either CRH or UCN increased blood pressure, but only UCN increased heart rate.

The administration of CRH and UCN could be expected to increase salt intake due to their stimulatory influence on the secretion of ACTH or activity of the sympathetic nervous system. It appears that the hormones associated with stress may have both excitatory (ACTH and adrenal hormones) and

Figure 5 The effect of intracerebroventricular (ICV) infusions of aCSF, UCN, CRH, and ACTH on 0.5 M NaCl intake in sheep. * indicates $p < 0.05$. aCSF, artificial cerebrospinal fluid; ACTH, adrenocorticotropic hormone; CRH, corticotropin releasing hormone; UCN, urocortin.

Figure 6 The effect of intravenous (IV) infusions of NSal, UCN, CRH, and ACTH on 0.5 M NaCl intake in sheep. ACTH, adrenocorticotropic hormone; CRH, corticotropin releasing hormone; NSal, normal saline; UCN, urocortin.

inhibitory (CRH and UCN) influences on salt intake. At present, the explanation for the inhibitory influence of CRH and UCN is not known. Presumably, the inhibition of salt appetite is caused by the influence of CRH on systems other than those influencing ACTH secretion or sympathetic nervous activity.

Combined infusion of Urocortin and Adrenocorticotrophic Hormone

The observation that CRH and UCN increased the secretion of ACTH, as evidenced by the increase in plasma cortisol but decreased salt appetite, suggested that ACTH-induced salt appetite was inhibited. Administering the two peptides together tested the possibility that UCN inhibits ACTH-induced salt appetite. Indeed, the ACTH-stimulated salt intake was completely blocked by UCN, administered into either the brain or the circulation (see [Figure 7](#)). Additional observations indicated that UCN, given systemically, reduced the increase in blood pressure and enhanced the increase in heart rate caused by ACTH. In contrast, UCN, administered in the brain, did not alter the increase in blood pressure or the increase in heart rate caused by ACTH. The mechanisms responsible for the inhibitory role of UCN on salt appetite are still unknown. However, it is thought that UCN may play a role in steroid-induced salt appetite at the amygdala.

It is notable that prolonged peripheral treatment with a combined infusion of ACTH and UCN produced a marked increase in heart rate (see [Figure 8](#)), which was at least additive in magnitude when compared with heart-rate increases due to the infusion of either hormone alone. Plasma cortisol was also

elevated with both the central and peripheral infusions of UCN in conjunction with the peripheral administration of ACTH. The major increase in heart rate in response to the combined administration of peripheral ACTH and UCN is probably via the direct action of CRH-R2 receptors on the heart. The inhibitory effect of UCN on blood pressure may be explained by the UCN-induced secretion of natriuretic peptides, molecules that increase excretion of sodium. These results indicate that sympathetic nervous system control of the cardiovascular system cannot be the only mechanism responsible for these stress hormone-induced changes. See [Table 1](#).

Brain Mechanisms Involved in Stress-Induced Salt Appetite

Although the brain mechanisms responsible for salt appetite induced by stress have not yet been conclusively identified, there are several major candidates. The first involves midline brain tissue located on the front wall of the third ventricle (a donut-shaped, fluid-filled cavity). The circumventricular organs (i.e., the subfornical organ and the OVLT), notable for their lack of blood-brain barrier, are thought to be crucial to body fluid and mineral homeostasis in rats. A lesion to either of these areas causes a marked reduction in salt intake by the salt-depleted animal. However, sheep with lesions in this brain area responded normally to salt depletion. Evidence also indicates that these brain areas may contribute to salt appetite induced by treatment with the mineralocorticoid hormones. For example, there appear to be mineralocorticoid receptors within these brain regions and deoxycorticosterone treatment

Figure 7 The effect of intracerebroventricular (ICV) and intravenous (IV) infusions of UCN on ACTH-induced 0.5 M NaCl intake in sheep. ACTH, adrenocorticotrophic hormone; UCN, urocortin.

Figure 8 The effects of peripheral ACTH and central UCN infusions in sheep on a, blood pressure; b, heart rate; c, plasma cortisol concentration. ACTH, adrenocorticotrophic hormone; ICV, intracerebroventricular; IV, intravenous; MAP, mean arterial pressure; UCN, urocortin.

increases neuronal activity at these brain areas. However, salt appetite induced by treatment with deoxycorticosterone is unchanged or enhanced in rats with lesions of this brain region.

The second candidate involves brain regions located some distance from the midline and behind the

blood-brain barrier – the amygdala and bed nucleus of the stria terminalis. These brain areas are involved in the neural and hormonal responses to stress, especially those related to fear and anxiety. Increased neuronal activity has been reported in the medial amygdala of animals subjected to stress. Interference with mineralocorticoid receptor formation, with antisense to its mRNA, in the amygdala has been shown to interfere with the expression of deoxycorticosterone-induced salt appetite. Rats with lesion of the medial amygdala have impaired aldosterone and deoxycorticosterone-induced salt appetite, and the corticosterone potentiation of aldosterone-induced salt appetite is eliminated. Despite the evidence that salt appetite caused by salt depletion is mediated by the synergy between aldosterone and angiotensin II, rats with lesion of the medial amygdala do not have impaired salt appetite caused by salt depletion. Rats with lesion of the central nucleus of the amygdala or the bed nucleus of the stria terminalis (an area of brain intimately related to the central nucleus of the amygdala and often called the extended amygdala) show deficits in both deoxycorticosterone and salt-depletion-induced salt appetite. It seems clear at present that the several different brain areas mentioned earlier participate in the control of salt appetite. In rats, the subfornical organ and OVLT appear to be important to salt appetite caused by salt depletion, the medial amygdala seems to be important to salt appetite stimulated by the adrenocortical hormones, and the central nucleus of the amygdala and the bed nucleus of the stria terminalis seem to be involved in both. Further work is required to determine how these brain areas interact and what their roles are in modulating salt appetite during stress. Also, the brain mechanisms involved in salt appetite in other species still needs to be determined.

Conclusion

Overall, the data reviewed here show that stress can cause increased salt intake. Also, some, but not all, of the hormones associated with the stress response (e.g., ACTH and the adrenocortical hormones) can induce salt appetite. CRH and UCN inhibit salt appetite, even that caused by ACTH. The increased intake caused by ACTH appears to be mediated by the action of the adrenocortical hormones acting on receptors located in the amygdala and bed nucleus of the stria terminalis. At present, however, a role for adrenocortical hormones acting on receptors located in the circumventricular organs cannot be ruled out. An increase in angiotensin II or activity of the sympathetic nervous system caused by stress may also stimulate salt intake, possibly by the stimulation of the HPA

axis. The mechanisms responsible for the inhibitory actions of CRH and UCN are as yet unknown.

Hormones associated with the stress response also increase blood pressure, and evidence suggests that the enhanced intake of salt may augment any increases in blood pressure caused by the stress. For example, in rats, increased blood pressure caused by stress is augmented by high salt intake. Similar observations have been made in dogs and baboons. In humans, salt sensitivity and family history may also contribute to the effect of high salt intake on stress-induced hypertension.

Figure 4 depicts some of the mechanisms by which stress may influence both dietary salt intake and blood pressure. Other factors will no doubt emerge with further research, including species differences.

Glossary

<i>Adrenocorticotropin (ACTH)</i>	The pituitary hormone that stimulates the synthesis and secretion of adrenal corticosteroids and especially the glucocorticoids.
<i>Corticotropin-releasing hormone (CRH)</i>	The 41-amino-acid residue peptide released from hypothalamic neurons that mediates neural control of ACTH secretion. CRH has also been implicated in the central control of emotion and behavior.
<i>Dexamethasone suppression test (DST)</i>	A test designed to determine the responsiveness of the HPA axis to the negative feedback effects of the potent synthetic glucocorticoid dexamethasone. Major mental disorder is often associated with a blunted response to the DST.
<i>Expressed emotion (EE)</i>	Emotion expressed by close relatives toward family members with schizophrenia.
<i>Hypothalamic-pituitary-adrenocortical (HPA) axis</i>	The system that involves CRH-induced ACTH release, which in turn leads to adrenal glucocorticoid secretion. The latter moderates ACTH release by way of negative feedback regulation.
<i>Magnetic resonance imaging (MRI)</i>	An imaging technique commonly used primarily to produce high-quality images of brain.

Ultra-high risk (UHR) A cohort of individuals identified as being at ultra-high risk to develop psychosis.

Introduction

Stress may have an impact on the course and severity of schizophrenia during a number of stages along the neurodevelopmental trajectory, including presymptomatic and early symptomatic phases as well as the phases associated with chronicity and relapse. Extensive neurobiological research has now identified molecular pathways and brain regions that are likely to be involved in the interplay between stress and schizophrenia. The interaction between these pathways has not, however, been the subject of pharmacological intervention studies. Most of the therapy-oriented research in this field has involved psychosocial approaches to reducing stress and minimizing the impact of life events in order to reduce symptom severity and the risk of relapse.

Schizophrenia: Definition and Etiology

Schizophrenia is an enigmatic illness of unknown cause, heterogeneous symptomatology, and unpredictable course, with a variable treatment response. While the precise definition of schizophrenia poses numerous difficulties, there is general agreement that the disorder involves a breakdown of integration among emotions, thoughts, and actions due to underlying neurobiological abnormalities. Common symptoms include disorganized thought processes, hallucinations, delusions, inappropriate or blunted affect, social withdrawal, and poverty of speech. Cognitive impairments, including deficits in working memory, attention, and executive functioning are also often found in the disorder. Because many of these symptoms occur in other disorders, they cannot be regarded as diagnostic when taken individually. According to most diagnostic systems, the diagnosis of schizophrenia requires specific psychopathologies to be present for at least 6 months.

The onset of schizophrenia is usually during late adolescence or early adulthood. Gender differences exist, with women on average having a later onset and a more benign course of the illness. The lifetime prevalence of schizophrenia is around 1% of the general population across all ethnic backgrounds, nationalities, and socioeconomic classes. Most people with the disorder are unemployed. Many live in substandard

accommodation and experience drug or alcohol dependencies. Approximately 10% of people with schizophrenia commit suicide. Thus, schizophrenia represents a significant public health problem, from both an economic and a social point of view.

The Effects of External Stressors: Expressed Emotion and Life Events

Genetic factors play a major role in the development of schizophrenia; however, they alone do not explain the illness. First, multiple genes appear to be involved in the etiology of schizophrenia, collectively increasing susceptibility to the illness but each contributing only a small percentage to the risk. Furthermore, while family, twin, and adoption studies strongly support this genetic contribution, the finding of only 35–50% concordance for schizophrenia among monozygotic twins clearly supports the involvement of environmental factors. Epidemiological studies have identified several such adverse factors that may increase incidence of schizophrenia, such as pre- or perinatal obstetric complications, maternal influenza or rubella infection, or malnutrition and psychological trauma during pregnancy. For example, among both men and women conceived at the height of the Dutch famine in 1945, the risk of later developing schizophrenia was double that of individuals born before or after this period. Prenatal exposure to famine was also associated with decreased intracranial volume and white matter hyperintensities. These data have now been confirmed in a separate Chinese study, in which it was found that prenatal exposure to the 1959–61 famine more than doubled the risk of later developing schizophrenia. Both studies thus show that early stress caused by prenatal nutritional deficiency may play a role in the pathogenesis of schizophrenia. It should be noted that other nonstress factors could also play a role in the apparent link between famine and schizophrenia.

In addition to early environmental disturbances causing an increased risk, environmental factors later in life, such as drug abuse or psychosocial stress, may precipitate the disorder in predisposed individuals. For example, there is a significant relationship between the use of drugs of abuse, such as cannabis, and the exacerbation of psychosis and schizophrenia. The common denominator of all these early and late environmental factors is that they all induce stress, i.e., increased central and systemic release of stress hormones and disturbance of physiological and neurochemical homeostasis. The development of schizophrenia therefore may involve a disruption of

early development, by either genetic or stress factors, which induces subtle changes along the neurodevelopmental trajectory. These changes could take place in synaptogenesis, synaptic pruning, axonal myelination, and neuronal proliferation in various brain regions, including cortex and hippocampus, but if they precede the onset of the disorder they either remain silent until the onset of the disorder or lead to very minor neuropsychiatric or behavioral changes in childhood and adolescence. Such changes have been reported and include a tendency for delayed neurological development, reduced social functioning, lower IQ, and neurological soft signs. However, while these associations are statistically significant, many individuals in the normal population also display such abnormalities. As a result, the presence of such mild abnormalities is not of clinical utility in the prediction of the development of schizophrenia. The emergence of psychotic symptoms may be triggered by additional stress, which may also be responsible for a later aggravation or reemergence of symptoms. One of the most influential versions of the neurodevelopmental hypothesis of schizophrenia thus comprises at least two principal components, highlighting postulated early changes in the brain, followed by later disturbances in psychological and physiological homeostasis – the so-called two-hit hypothesis of schizophrenia.

Early attempts to characterize the existence of stress-reactive schizophrenia were driven by the finding that attempts to overcome negative symptoms by social stimulation sometimes induced the reemergence of positive, psychotic symptoms of schizophrenia. This has since been tested through the study of expressed emotion (EE) – emotion expressed by close relatives toward family members with schizophrenia. Many, but not all, studies have shown that patients who experience a family environment with high EE, especially of a type that is chronic and critical in nature, have a greater propensity for psychotic relapse compared to patients from families with lower levels of EE.

Although EE studies have provided some of the strongest evidence for the stress reactivity of schizophrenia, the EE measure has been frequently misunderstood and misapplied. One of the most common mistakes is to conclude that critical and overinvolved caregivers are the major cause of poor clinical outcomes, with the result that family members are blamed for causing or exacerbating the illness. Such an approach fails to take into account the iterative relationship between high EE and patient relapse, which includes the impact of psychiatric illness on

the patient's carers. In support of the iterative nature of this relationship is the established correlation between EE and family burden.

In comparison to EE, which is relatively ambient and consistent, thereby providing a probe for the impact of chronic stress on schizophrenia, life events are more discrete and less predictable, thereby providing a greater insight into the effect of acute stress on the condition. Although the majority of studies support an association between the propensity to experience episodes of schizophrenia and either the frequency of both major life events and daily hassles or their negative subjective appraisal, most of these studies have been retrospective and could therefore be affected by a search after meaning, which leads individuals to bias their recall in favor of giving undue importance to life events in order to explain their psychotic symptoms.

The anxiety associated with the psychotic experience itself may also contribute to relapse and symptom severity. Clearly, responses to delusions of persecution and danger or to hallucinations of a derogatory and intrusive nature may involve severe distress, which in turn may further exacerbate psychotic symptoms.

The Hypothalamic-Pituitary-Adrenocortical (HPA) Axis and Schizophrenia

There is good evidence that HPA axis dysfunction, as evidenced by nonsuppression in the dexamethasone suppression test (DST), occurs in approximately one in five subjects with schizophrenia, which is more than in normal subjects but less than in patients with depression. Post mortem studies have shown reduced glucocorticoid receptor expression in the hippocampus of subjects with schizophrenia, which might contribute to reduced negative feedback to the HPA axis and thus play a role in DST nonsuppression.

DST nonsuppression appears to be more common in patients who are in the acute or initial phases of their illness than in stable or chronic phases. This may explain some inconsistency in the literature, which could be attributable to differences between prodromal, first episode, and chronic patients. In addition, antipsychotic treatment has been shown to normalize at least some of the HPA axis disturbances, such as nonsuppression in the DST. The initial phase of psychosis has been shown to be associated with HPA axis hyperactivity, shown by elevated circulating cortisol cerebrospinal fluid CRH levels and impaired DST. First episode patients show enlarged pituitary volumes as measured by magnetic resonance imaging (MRI). This might reflect HPA axis hyperactivity, since

enhanced CRH and adrenocorticotropin (ACTH) secretion leads to increased size and number of pituitary ACTH-producing cells. These effects could be the consequence of the previously mentioned distressing psychotic experience or, alternatively, could be involved in the induction of psychosis. To distinguish between these possibilities, pituitary volumes have been measured in a cohort of individuals identified as being at ultra-high risk (UHR) to develop psychosis. Importantly, these subjects were symptom-free and did not receive antipsychotic medication at the time of pituitary volume measurement. Within this UHR cohort, pituitary volume positively predicted future transition to psychosis, and subjects with the greatest increase in pituitary volume also showed the shortest time between being scanned and psychosis onset. Theoretically, UHR individuals with enlarged pituitary volumes might benefit from preventative treatments that target HPA axis overactivity, such as glucocorticoid receptor antagonists or CRH receptor antagonists.

While there is clear evidence for disturbances in HPA axis function in a subset of individuals with schizophrenia, the mechanism by which these disturbances mediate illness development and symptomatology is less clear. Chronically enhanced levels of glucocorticoid hormones are neurotoxic, for example, leading to macroscopic volume reduction and cell loss in the hippocampus as well as reduced neuronal volume and dendritic arborization. These effects could be associated with some of the cognitive impairments seen in patients with schizophrenia and could also explain some of the structural changes seen in the brains of patients with schizophrenia, such as reduced cortical and hippocampal volumes.

There appears to be a synergistic relationship between HPA axis activity and dopaminergic activity in the brain. Glucocorticoids increase dopamine metabolism in the striatum and dopamine release in the nucleus accumbens. If these effects apply to all areas of the brain, HPA axis disinhibition is likely to contribute to dopaminergic hyperactivity, which appears to be central to psychosis symptomatology. Positron emission tomography studies have shown that patients with schizophrenia display greater increases in central dopamine release in response to certain challenges, including low-dose amphetamine. All antipsychotic drugs share dopamine receptor antagonism as part of their pharmacological mode of action. Conversely, abnormalities in dopaminergic activity influence HPA axis activity and render an individual hyperresponsive to stress. The vulnerability-stress model of schizophrenia suggests that the illness is potentiated by stress due to this interplay with brain dopaminergic activity.

Stress, Early Development, and Schizophrenia: Neurobiological Findings

In an attempt to elucidate neurobiological mechanisms involved in the interaction of environmental factors and schizophrenia, animal model studies have simulated major life events during early stages of development. These animals, mostly rats, are then tested as adults in behavioral paradigms with relevance to schizophrenia. Developmental disruptions include neonatal stress induced by maternal deprivation, prenatal maternal stress, developmental stress induced by placental insufficiency, antimitotic treatment or vitamin D depletion, and prenatal or neonatal infection. Several studies have also used neonatal brain lesions, such as in the ventral hippocampus, frontal cortex, or amygdala. Such early interventions induce behavioral effects in the adult such as hyperlocomotion, enhanced sensitivity to psychotomimetic drugs (amphetamine, phencyclidine), disruptions of pre-pulse inhibition, and learning and memory deficits.

Another approach has been to study the influence of variations in maternal care. In these rat studies, dams were classified according to the level of maternal care, and behavioral and molecular changes in the offspring were examined. Offspring from mothers that displayed high levels of pup licking, grooming, and nursing differed in the level of DNA methylation from offspring from mothers that displayed low levels of these behaviors. These effects persisted into adulthood and resulted in specific changes in the regulation of glucocorticoid receptor expression. Offspring from mothers that displayed lower levels of maternal care showed lower levels of glucocorticoid receptor expression and greater plasma corticosterone increases to stress than offspring from mothers that displayed higher levels of maternal care. These studies show that early environmental factors, in this case the level of maternal care, induce long-term molecular and biochemical alterations leading to differences in glucocorticoid receptor expression and alterations in HPA axis activity. Such changes in stress responsiveness could be involved in the role of stress in schizophrenia.

Treatment Implications of the Vulnerability-Stress Model of Schizophrenia: Psychosocial Treatment Strategies

Psychosocial treatments are critical elements in the management of schizophrenia, provided that they are – as they need to be – in tandem with the key-stone of treatment, antipsychotic medication. Stress management has received relatively little research

attention in the treatment of the disorder, but there are suggestions that this form of treatment reduces the prevalence of hospitalization. Psychosocial treatment modalities that have received greater validation include family therapy, assertive community treatment, psychoeducation, social skills training, and cognitive-behavioral therapy. To the extent that these modalities improve coping skills, the positive outcomes they have been associated with in terms of relapse prevention and symptom amelioration might, in part, be a consequence of reduction in stress levels.

Conclusion

A variety of epidemiological, clinical, and neurobiological studies have suggested a nontrivial link between stress and schizophrenia, both during development and during the initial and established phases of the disease. These studies provide clues about brain mechanisms that could be the target of future new pharmacological treatments and about psychosocial strategies aimed at enhancing coping skills and reducing the impact of stress on the individual. However, as the available evidence is still controversial, further studies are clearly needed to better our understanding of the role of stress in schizophrenia.

- School refusal behavior* The substantial child-motivated refusal to attend school and/or difficulties remaining in classes for an entire day.
- School stress* Unpleasant physical and cognitive symptoms in response to global and specific school-related stressors.

School Stress and Linkage to School Refusal Behavior

Children and adolescents become anxious about many things, but youths become particularly stressed by difficult family and school situations. School-related stressors may involve global and specific issues. Global school-related stressors include large class size, threats of victimization and violence, changes in academic and social status, excessive

homework, and tedious curricula. Specific school-related stressors include teachers and other school officials, peer interactions, examinations, performances before others, social gatherings, and use of cafeterias and public restrooms.

School-related stressors are quite prevalent among youths, and many youths experience concomitant physiological and cognitive symptoms as a result. Common physiological symptoms include headaches, stomachaches, shortness of breath, trembling, dizziness, and heart palpitations. Common cognitive symptoms include catastrophic thoughts about losing control, going insane, suffering humiliation or harm, experiencing negative evaluation from others, appearing foolish, having few friends, having trouble concentrating, and lacking competence in various areas. If school-related stress becomes severe, then some youths may refuse to attend school to avoid these unpleasant symptoms.

Major Characteristics of School Refusal Behavior

School refusal behavior is the substantial child-motivated refusal to attend school and/or difficulties remaining in classes for an entire day. Specifically, the behavior involves youths ages 5–17 years who (1) are completely absent from school, (2) attend school but then leave school during the school day, (3) go to school following intense behavior problems such as tantrums in the morning, and/or (4) display unusual distress during the school day that leads to pleas for future nonattendance. School refusal behavior may also be defined by its timeline. For example,

self-corrective school refusal behavior refers to absenteeism that remits spontaneously within 2 weeks. Acute school refusal behavior lasts from 2 weeks to 1 year, and chronic school refusal behavior lasts longer than 1 year. Greater chronicity is related to greater difficulty reintroducing a child to school.

Approximately 5–28% of school-age youths refuse school at some time in their lives. School refusal behavior is seen equally in boys and girls and among families of various income levels. The short-term consequences of school refusal behavior include declining academic status, social alienation, increased risk of legal trouble, family conflict, and severe disruption in a family's daily routine. The long-term consequences of school refusal behavior include school dropout and subsequent economic deprivation, occupational and marital problems, alcohol abuse and criminal behavior, and mental disorders.

School refusal behavior is marked by considerable symptom heterogeneity. Common internalizing problems include general and social anxiety/shyness, depression and social withdrawal, fear, fatigue, and somatic complaints such as stomachaches, headaches, nausea, and tremors. Common externalizing problems include tantrums, verbal and physical aggression, clinging, reassurance seeking, refusal to move, noncompliance, and running away from school or home.

School refusal behavior is also marked by many different diagnoses that could cause or be the result of problematic absenteeism. In this population, common comorbid diagnoses include separation anxiety disorder, generalized anxiety disorder, depression, and oppositional defiant disorder, among others. In addition, school refusal behavior has been linked to limited developmental disabilities such as learning disorders and pervasive developmental disabilities such as Asperger's disorder, autism, and mental retardation.

Etiology and Major Functions of School Refusal Behavior

The specific causes of school refusal behavior are often unclear for a particular case. However, common triggers include the onset of a new school year, entry into a new school building, school-related trauma, teacher or class changes, family illness or transition, parental psychopathology, and marital conflict or divorce. Child factors such as behavioral inhibition, excessive shyness, and association with deviant peers can also be influential. Unfortunately, identifying the etiology in this population is often a fruitless task. As such, clinicians may focus instead on the primary functions or reasons why youths refuse school:

1. To avoid school-related objects and situations that provoke a general sense of negative affectivity (dread, anxiety, depression, and physiological symptoms).
2. To escape aversive social and/or evaluative situations at school.
3. To receive attention from significant others outside of school.
4. To obtain tangible reinforcement outside of school.

The initial two functions refer to youths who refuse school for negative reinforcement, or to avoid something unpleasant at school. These functions are closely related to the concept of school stress. The latter two functions refer to youths who refuse school for positive reinforcement, or to pursue someone or something more alluring outside school. Some youths also refuse school for multiple reasons, and those who do often require complex and extended treatment.

Assessment of School Refusal Behavior

Assessing youths with school refusal behavior often involves defining a child's exact behavior problems, discovering primary and secondary functions for absenteeism, and identifying effective treatment. To do so, assessment methods may include interviews, child self-report and parent/teacher measures, direct observation, daily monitoring, and discussions with school officials. Interviews may be structured or unstructured in nature. A common structured interview for this population is the Anxiety Disorders Interview Schedule for Children, which has child and parent versions and helps clinicians identify various diagnoses. In addition, the interview contains a special section on school refusal behavior to help clinicians pinpoint the frequency and intensity of the behavior and related stress-based symptoms. Unstructured interviews may also be used to assess youths with school refusal behavior. Questions may relate to school-related stressors that affect a particular child, degree of avoidance, physiological and cognitive symptoms, attention-seeking, and pursuit of tangible reinforcers outside of school.

Several child self-report and parent and teacher measures also pertain to youths with school refusal behavior. The most common address negative affectivity, depression, general and social anxiety, somatic complaints, overactivity, aggression, noncompliance, demands for attention, social problems, fear, self-concept, family dynamics, and the function of school refusal behavior. Gathering information from multiple sources is recommended because school refusal behavior can include many subtle symptoms.

Direct observation of a child's and family's morning activities at home may also help define the primary symptoms and maintaining variables of school refusal behavior. Pertinent behaviors include:

1. Avoidance in the form of clinging, refusal to move, running away, and/or noncompliance to requests.
2. Physiological reactivity such as stomachaches, headaches, abdominal pain, tremors, and nausea/vomiting.
3. Cognitive distortions or verbalizations about discomfort related to school.
4. Sudden changes in behavior.
5. Pleas to stay home from school.
6. Increased family conflict, especially following a curtailment of the child's social activities.
7. Significant changes in parental behavior.
8. Teacher reports of differences in a child's behavior at school.

The daily assessment of a child's school refusal behaviors and attendance is also important. This helps gauge familial compliance to homework assignments, increase insight into a child's problem, and identify positive or negative changes in behavior across time. For example, family members may provide daily ratings with respect to a child's anxiety, depression, and overall distress (general feelings of dread or being upset). In addition, parents may rate a child's noncompliance (not listening to parent commands) and disruption to their daily routine. Parents can also list other child behavior problems and time missed from school.

Finally, school officials may be contacted for additional information, including course schedules, grades, written work, and required make-up work; goals and attitudes of school officials and peers regarding a child; procedures and timelines for reintegrating a child into school; potential obstacles to reintegrating a child into school; confirmation of past school refusal behavior; general social or other behaviors of a child in school; a map or outline of the school (e.g., lockers, cafeteria, library); feedback about treatment effectiveness; disciplinary procedures and procedures for contacting parents; and rules about absenteeism, conduct, or leaving school areas.

Treatment of School Refusal Behavior

Treatment for youths with school refusal behavior may be linked to the function of the behavior. For example, treatment for youths who refuse school to avoid stimuli provoking negative affectivity (i.e., school stress) often involves reducing unpleasant physiological symptoms and exposing a child to

various school-related items and situations. Specifically, this involves psychoeducation about the nature and process of anxiety (i.e., linking feelings, thoughts and behaviors), developing an anxiety and avoidance hierarchy of situations and stimuli, teaching somatic management skills to decrease negative emotional arousal (i.e., relaxation training and breathing retraining), systematic imaginal and *in vivo* exposure to anxiety cues identified on a graded hierarchy (progressive reintroduction to the school setting), and having a child praise him- or herself for coping with transient negative emotions.

For youths who refuse school to escape aversive social and/or evaluative situations, treatment strategies involve building or refining social skills and reducing social anxiety in key interactive situations at school. Specifically, this involves psychoeducation about the nature and process of anxiety (i.e., linking feelings, thoughts, and behaviors), teaching a child to identify cognitive distortions (e.g., all-or-none thinking, catastrophization, and overgeneralization) and negative self-statements in anxiety-provoking situations, learning methods to change distorted thoughts to helpful coping thoughts, graduated exposure to anxiety-provoking social situations through in-session practice with a therapist (including modeling and role-play of different situations), and between-session practice of skills in real-life social situations.

For youths who refuse school for attention, treatment strategies involve parent-based techniques to shift parental attention away from school refusal behaviors and toward appropriate school attendance behaviors. Specifically, this involves restructuring parent commands, establishing fixed routines regarding a child throughout the day, implementing negative consequences for school refusal behaviors, implementing positive consequences for school attendance behaviors, and, in some cases, forced school attendance.

For youths who refuse school for tangible reinforcement outside school, treatment strategies involve improving a family's problem-solving abilities, reducing conflict, increasing rewards for school attendance, and decreasing rewards for school absenteeism. Specifically, this involves establishing times and places when family members can negotiate problem solutions, defining behavior problems specifically, designing written parent-child contracts to address problems, implementing contracts, training in communication skills, training in peer-refusal skills (i.e., helping a child refuse offers to miss school), and escorting a child to school or to each class. For all treatments, relapse-prevention training is also necessary.

Hostile School Behavior: Prevalence and Concerns
Connection between Bullying and Violent Offending
Antecedents and Consequences of Hostile Experiences
The Effects of Witnessing Hostile Behaviors

Bullying and school violence are significant sources of stress in American schools. In a recent national survey, children ages 8–15 rated bullying as one of the major concerns affecting their lives. Another survey indicated that almost two-thirds of public secondary school students thought that a shooting could take place in their school.

In contrast to violent behaviors that involve use of physical force, bullying entails the abuse of psychological strength, which can be achieved by various means. Bullies intimidate their victims by relying on name-calling, exclusion, threats, and/or spreading of rumors. Because the perpetrators of violent acts as well as bullying abuse their power, both forms of hostile behavior cause psychological distress in that the actual and potential victims of peer maltreatment or abuse experience anxiety. Repeated experiences of hostile behavior by schoolmates are, in turn, associated with increased feelings of depression and either withdrawn or aggressive behavior.

Hostile School Behavior: Prevalence and Concerns

According to the most recent national data, 14% of students ages 12–18 reported having been bullied in school during the previous 6 months. The estimates for bullying vary depending on how broadly the term is defined and the time frame provided. Using daily (as opposed to monthly or yearly) reports of bullying experiences, almost 50% of young teens reported at least one incident of bullying during a 2-week period in urban middle schools. Up to 70% of secondary students reported having experienced bullying at some point during their school careers. Although the experiences of bullying are fleeting for most students, an estimated 5–10% of students confront bullying on a weekly, if not daily, basis for 1 or more school years.

The prevalence estimates of bullying also vary by grade level and school type. Compared to other grade levels, middle school students reported the highest rates of bullying, and sixth-grade students were most fearful of their safety. Although girls reported being more concerned about their safety at school or on their way to and from school, boys reported more incidents of violence and bullying. Boys were also the perpetrators of the most violent incidents.

Approximately 70% of public schools reported one or more violent incidents during a school year. Although the most serious forms of violence are less common, one-fifth of public schools reported at least one incident involving aggravated assault, sexual assault, rape, or robbery per year. Violent incidents

are most likely to take place during the high school years and in large urban schools.

Students in urban public schools are most likely to fear for their safety. Black and Latino students reported feeling more fearful of being attacked than did White students. Although some hostile incidents appeared to be racially motivated, this does not necessarily mean that students were worst off in ethnically mixed schools. Recent analyses of middle schools suggest that greater ethnic diversity (i.e., a larger number of ethnic groups and their relative balance) is associated with feelings of safety.

Connection between Bullying and Violent Offending

Children who bully in childhood are at risk of becoming violent offenders. Research conducted in Norway shows that boys identified as bullies in their teenage years were four times as likely to commit violent acts in their twenties than other boys. Long-term studies conducted in the United States reveal that when childhood bullying is associated with more serious subsequent fighting, the risk of committing assaults and rape significantly increases. Hence, at least the physical forms of bullying and violent offending among males reflect a spiral of increasingly serious hostile behaviors.

Both childhood bullying and school violence are predicted by personality dispositions (e.g., impulsivity), environmental factors beyond school (e.g., problematic relationships with parents), and school-related situations (e.g., perceptions of unfair treatment by teachers or peers). These risk factors often interact in that students with certain dispositions are more likely to encounter situations that prompt them to act aggressively. For example, impulsive students are likely to act in a way that increases their chances of someone's bumping into them in a hallway, and, after experiencing an unintended push, they are more likely to react with hostility. The hostile response is often promoted by a perception that the other person intended to cause harm.

Many aggressive students develop a generalized sense of mistrust. Hence, students commit hostile acts to protect themselves. For example, compared to non-bullied students, bullied students are more likely to carry a weapon to school. Fear for their safety is the most common reason provided by students who carry weapons to school.

Other students' hostile acts are motivated by a desire to maintain a sense of control and to show their power. These bullies or violent offenders enjoy at least temporary admiration among their peers because of their dominant status. Fellow students rarely

challenge their mean and hurtful behaviors because they are fearful of the reactions of these dominant ringleaders. Passivity and acceptance of toughness, in turn, promote social norms that encourage and maintain bullying or even violent behavior. Thus, the school environment, including the reactions of fellow peers (victims or bystanders), plays a critical role in motivating hostile behavior in school.

Antecedents and Consequences of Hostile Experiences

Because of the low prevalence rates of serious violent incidents in school, little is known about the factors that increase the risk of being targeted. However, research on bullying shows that socially withdrawn and passive children are at risk of getting bullied. After repeated experiences of bullying, these submissive victims become even more withdrawn. These students most often suffer in silence, and teachers and parents are unaware of their plight or distress. Instructors may interpret the quiet signs of distress as a lack of interest in schoolwork. Indeed, teachers rate victims as being just as disengaged from schoolwork as bullies.

Students who respond to bullying with unregulated aggression (i.e., aggressive victims) are also at a high risk for continued peer maltreatment. In these cases, bullying experiences are related to extreme peer rejection and severe school difficulties. Aggressive victims are presumed to have underlying emotional difficulties, which are also used to help explain why their difficulties continue. Thus, in the cases of both submissive and aggressive victims, the causes and consequences of bullying form a vicious circle.

Although aggressive victims resemble violent offenders most closely, the victims of bullying are unlikely to resort to violence to get back at their tormentors. Nevertheless, the tragic school shooting incidents since the late 1990s highlight that chronic victims of bullying, like violent offenders, have trouble effectively dealing with social failures (e.g., public ridicule or rejection by a romantic partner). Some violence prevention and antibullying interventions are therefore specifically designed to help students better cope with bullying incidents.

The Effects of Witnessing Hostile Behaviors

The hostile behaviors of schoolmates affect not only those who are victimized but also those who witness peer abuse or maltreatment in school. For example, analyses of daily incidents of bullying in middle school show that social anxiety is increased when students see someone else being bullied. Students

who witness violent incidents are likely to feel especially vulnerable and unsafe. Thus, although there may be relatively few hostile students in any one school, one or two can terrorize entire grade levels and a couple of violent events may cause widespread fear. In view of such exposure effects, the level of concern about bullying and violence in American schools is not unrealistically high.

Part of the distress caused by observed events is likely to be related to the school's response system (or lack thereof). Although the parents' concerns about the safety of their children at school may be alleviated by the presence of metal detectors and campus officers, students continue to worry about their safety because they know that someone can smuggle a weapon to campus or they are fearful of someone bullying them in sites lacking monitoring (e.g., restrooms and locker rooms). In addition to feeling vulnerable, an unsafe or noncaring school climate is likely to breed mistrust and alienation that, in turn, increase the risk of students carrying weapons and setting off a hostile response.

In summary, school violence and bullying cause, and are also partly caused by, feelings of vulnerability that reach beyond personal experiences of hostile acts. This can be depicted as a following process:

Perceived vulnerability of self → Hostile
response to perceived threat → Unsafe school
climate

To promote feelings of safety and trust, schools are relying more and more on prevention models that focus not only on at-risk youth but also on

helping improve the school climate. A caring climate in schools, in which students feel they belong, are respected, and are listened to and in which teachers help mediate hostile incidents, can buffer the safety concerns and distress of the entire student body.

Introduction

Seasonal Energetic Adaptations

Seasonal Adjustments in Glucocorticoid Secretion

Why Are Stress Responses Seasonally Variable?

Glossary

Glucocorticoids

A class of steroid hormones secreted from the adrenal cortices that serves to promote energy use. Corticosterone is the glucocorticoid usually secreted by rodents and birds, whereas cortisol is typically secreted by primates.

Melatonin

An indole-amine hormone secreted from the pineal gland at night that is important in the regulation of daily and seasonal biological rhythms.

Photoperiod

Day length or the amount of light per day.

<i>Photo-periodism</i>	The response of plants to the length of day and night, including the ability to determine day length (usually by measuring night length) in both plants and animals; first proposed by botanists Garner and Allard in 1922.
<i>Pineal gland</i>	An endocrine gland that secretes melatonin, usually located between the telencephalon and diencephalon in vertebrates; also called the epiphysis.

Introduction

Stressors are not constant but, rather, vary over time. In addition to daily changes in stress, seasonal changes in the quality and quantity of stress are common. Many energetic adaptations have evolved that attenuate the stress response during the winter when energy shortages may limit the ability of organisms to cope successfully with specific types of stressors. The temporal organization of such stress responses therefore must be considered to obtain a holistic understanding of the mechanisms underlying the stress response.

The main endocrine features of the stress response involve hormones that act to suppress energy storage and promote energy utilization from adipose and liver stores. Epinephrine and the glucocorticoids are the major hormonal components of the stress response. Animals require a relatively steady supply of energy to sustain biological functions. Although these energy demands are somewhat continual, both daily and seasonal fluctuations in energy requirements occur as physiological and behavioral activities wax and wane. Animals typically do not feed continuously to supply energy to cells; rather, adaptations have evolved to allow animals to store and conserve energy when they are engaged in nonfeeding activities. Eventually, however, the chronic need for energy depletes these stores and requires animals to obtain food. In most habitats, significant daily and seasonal fluctuations in food availability occur. For example, outside of the tropics, food availability is generally low during the winter when thermogenic energy demands are typically high. Consequently, energy intake and energy expenditures are never perfectly balanced because of fluctuations in both energy requirements and availability. Whenever a significant imbalance of energy is perceived, a stress response in the form of secreted glucocorticoids ensues.

Reproduction is sufficiently demanding that a stress response is often associated with breeding in terms of elevated glucocorticoid concentrations. That is, glucocorticoids are released to support the energetic needs of reproduction including territorial defense or courtship behaviors. However, when

energy is insufficient to support reproduction and thermogenesis or other energetic demands, the stress response becomes prolonged. A chronic stress response results in pathology. Most animals restrict breeding to specific times of the year when food is abundant and survival and reproductive success are most likely. The inhibition of winter breeding is one of the central components of a suite of energy-saving seasonal adaptations evolved among nontropical animals. In addition to the seasonal onset and cessation of reproductive function among nontropical vertebrates, it is also well-established that endocrine, metabolic, growth, neural, immune, and thermogenic processes undergo seasonal changes to promote winter energy conservation. Mechanisms in virtually every physiological and behavioral system have evolved to cope with the winter energetic bottleneck resulting from increased thermogenic energy requirements during periods of low energy availability. Presumably, animals possessing these energy-conserving adaptations enhance their survival and ultimately increase their reproductive success. Generally, glucocorticoid concentrations are higher during the winter than the summer and individuals display more elevated stress responses during the winter than the summer. However, because coping strategies are engaged in anticipation of the winter stressors, many individuals do not show exaggerated stress responses during the winter.

How do animals determine time of year? In most cases, the photoperiod (day length) acts as the principal external cue to determine time of year. Photoperiod measurement is important for organizing the seasonal collapse and regrowth of the reproductive system in mammals and birds from temperate and boreal latitudes. Indeed, changes in day length provide the most error-free signal for predicting favorable conditions. Day length is encoded by the hormone melatonin, which is secreted primarily at night from the pineal gland.

Seasonal Energetic Adaptations

Many aspects of life are energetically challenging, and individuals have evolved timing mechanisms to parse out energetically demanding activities to different times of year. For example, birds engage in predictable cycles of migration, breeding, parenting, molting, and overwintering. These energetically expensive activities generally do not overlap, and, again, all these activities elicit classical stress responses (i.e., elevated activation of the hypothalamic-pituitary-adrenal (HPA) axis).

One 1936 study is particularly informative in understanding the basis of Selye's thinking about stress

responses. Rats were housed in low-temperature conditions for 2 days, 2 weeks, or 2 months. After 2 days in these conditions, Selye noted the hypertrophy of the adrenal cortex; reduced eosinophil (a type of immune cell circulating in the blood) numbers; and atrophy of the thymus, spleen, and lymph nodes. In other words, the rats exhibited a classic stress response. After 2 weeks in the low temperatures, it was discovered that rats no longer displayed these symptoms; essentially, they had become cold-adapted and could tolerate low temperatures without exhibiting any further stress responses. After approximately 2 months of exposure to low temperatures, however, the rats lost this acquired resistance to low temperatures and died.

This process of coping with stressors was termed the general adaptation syndrome (GAS), and consists of three stages: (1) the alarm reaction, (2) resistance, and finally, (3) exhaustion. During the alarm reaction, stressors are detected. Coping with the stressor occurs during the resistance stage. The exhaustion stage is characterized by the termination of the stress response and the onset of stress pathology, which in extreme cases can lead to death. Although Selye believed that the exhaustion phase was due to the termination of the stress response, current ideas about stress indicate that the pathological effects of stress are due to the prolonged activation of the stress response. These three stages of the GAS correspond to the response of the rats to low temperatures after 2 days (alarm reaction), 2 weeks (resistance), and 2 months (exhaustion), respectively. If individuals have the opportunity to gradually move to low temperatures or are allowed to prepare for low-temperature conditions by first being housed for 8–10 weeks in short day lengths, then no stress responses occur.

Seasonal Adjustments in Glucocorticoid Secretion

Glucocorticoids are released in response to stressful stimuli and can affect reproduction, digestion, growth, multiple types of immune function, and virtually any other physiological process that requires significant energy. Predictably, seasonal variation in glucocorticosteroid secretion is more often the rule than the exception, probably because of the pivotal role these hormones play in orchestrating the distribution of resources among competing physiological activities.

Most animals studied to date display some seasonal variation in stress responses. For instance, Indian barnacles (*Balanus balanoides*) exhibit elevated antioxidant enzyme activity (a component of this species' stress response) prior to the monsoon season

compared with during it. Further, almost all wild amphibians, reptiles, and birds studied to date show marked changes in glucocorticoid concentrations during the year, with maximal values observed during the breeding season. Individuals of most mammalian species exhibit similar basal glucocorticosteroid concentrations year-round in the wild. However, this apparent pattern may reflect the paucity of studies on wild rodents rather than a lack of seasonality of this parameter. Indeed, rodents, such as deer mice (*Peromyscus* sp.), bred and maintained in the lab exhibit high corticosteroid concentrations when kept in long-day (breeding) conditions. Other species, however, such as Siberian hamsters (*Phodopus sungorus*), display elevated glucocorticosteroid concentrations when housed in short photoperiods.

Although it is clear from these studies that stress responses are temporally labile, two questions remain: (1) Is seasonal variation omnipresent within and among species (e.g., over a species' range) and (2) are other aspects of the stress response as seasonally labile as corticosteroid hormone concentrations? In terms of spatial variability, the results are mixed. Presumably, if photoperiod has significant effects on stress responses, then animals living at higher latitudes would exhibit higher circulating corticosteroid concentrations during breeding than animals at low latitudes simply because of the large variation in annual photoperiod. Redpolls (*Carduelis flammea*) are birds that live in the challenging arctic conditions of Alaska. Both males and females showed the typical marked elevation in blood corticosterone concentrations when captured for approximately 1 h, indicating that they responded similarly to many other vertebrates. However, the amount of the elevation in postcapture corticosterone varied across the year; corticosterone concentrations were generally blunted during January and maximal during June when birds were breeding. Generally, birds that had the highest fat stores secreted the lowest amounts of glucocorticoids postcapture. Similar patterns have been reported for other birds living at high latitudes, including the white-crowned sparrows (*Zonotrichia leucophrys gambelii*), snow buntings (*Plectrophenax nivalis*), and Lapland longspurs (*Calcarius lapponicus*). Across latitudes, however, results are mixed. Some species show little variability in circulating glucocorticoid concentrations (e.g., pied flycatchers, *Ficedula hypoleuca*, and mountain chickadees, *Poecile atricapilla*), whereas others (e.g., house sparrows, *Passer domesticus*, and white-crowned sparrows, *Zonotrichia leucophrys*) exhibit spatial variation. In common with spatial variability, the social system of animals can also affect seasonal variation in glucocorticoid responses. A study of greylag geese (*Anser anser*)

revealed that social status and physiological stress are not related in the same way in all seasons of the year.

In addition to hormones, other aspects of the glucocorticoid stress response show significant spatial and temporal flexibility. In particular, the HPA axis appears to be substantially malleable among wild songbirds. Individuals of different species can apparently modulate the levels of glucocorticoids they produce at different times of the year by changing the sensitivity of adrenergic tissues to upstream regulatory hormones such as corticotropin releasing hormone (CRH) or adrenocorticotrophic hormone (ACTH). Alternatively, some species are capable of modulating steroid-binding globulin levels in their blood across the year instead, although it remains unclear whether these globulins promote or inhibit the actions of the glucocorticosteroids to which they bind. Finally, corticosteroid receptors also appear to be seasonally variable. In house sparrows, membrane corticosteroid receptors are lowest during the nesting season, whereas cytosolic receptors are lowest during winter.

Why Are Stress Responses Seasonally Variable?

Presumably, stress responses help animals prepare for or recover from stressors. Why, then, are stress responses variable during the year when all individuals could benefit from optimal stress responses? Several hypotheses have been proposed. First, glucocorticoid stress responses are expensive and hence may not be affordable at all times of the year. Indeed, pyruvate, a readily usable energy source, blocked the stress-evoked suppression of cell-mediated and humoral immune activity in mice (*Mus musculus*). Second, high corticosterone concentrations, particularly when maintained for extended periods (i.e., chronic), can be immunosuppressive; over the short term, however, glucocorticosteroids can be immunoenhancing. In general, winter survival in small animals is expected to require a positive balance between short-day enhancement of immune defenses and glucocorticoid-induced immunosuppression. Immunosuppression caused by high glucocorticosteroids may be induced by many winter-related factors, including overcrowding, increased competition for scarce resources, low temperatures, reduced food availability, increased predator pressure, and lack of shelter. Moreover, winter breeding, with the potentially concomitant elevation in sex steroid hormones, may also compromise the immune system. Presumably, this explains why winter breeding predominantly occurs when other environmental stressors such

as temperature and food availability are not severe. Overall, the balance between enhanced immune function (i.e., to the point where autoimmune disease becomes a danger) and stress-induced immunosuppression (i.e., to the point where opportunistic pathogens and parasites overwhelm the host) must be met for animals to survive and become reproductively successful.

Several studies support this hypothetical construct. For instance, hamsters maintained in short photoperiods (and made to experience short-term stress) show more rapid wound healing and trafficking of leukocytes to the skin compared to unstressed short-day animals (or stressed and unstressed long-day hamsters). In one passerine bird, cutaneous immune responses to a T-cell mitogen (phytohemagglutinin, PHA) were less dramatic in animals induced into breeding than in those in a nonbreeding condition. Moreover, corticosterone appears to be immunosuppressive in the same species only in winter (not summer) conditions. Such immune–endocrine interrelationships are not always uniform between the sexes within a species. For example, acute stress enhances cell-mediated immune activity (delayed-type hypersensitivity to dinitrofluorobenzene) in female, but not male, Siberian hamsters. Indeed, ample evidence indicates that immune activity can vary dramatically between sexes; thus, it is plausible that the glucocorticoid mediators of immune defenses might be labile as well.

One other hormone that is integrally involved in vertebrate photoperiodism, melatonin, can affect the seasonal interplay between corticosterone and immune function. Generally, melatonin enhances immune activity, whereas glucocorticosteroids (at chronically high levels) compromise immune activity. Under certain circumstances, melatonin treatment may ameliorate the immunosuppressive effects of glucocorticosteroids. For instance, Siberian hamsters attenuated the duration of fever during simulated short winter day lengths, presumably to conserve energy. Hamsters housed in long days were injected with saline or melatonin before lights off each day for 1 or 6 weeks; then fever was assessed following injections of bacterial lipopolysaccharide (LPS). The fever duration was attenuated (32%) only in hamsters that decreased body mass, increased glucocorticoid concentrations, and displayed gonadal regression in response to 6 weeks of melatonin. These results suggest that long-term exposure to long-duration melatonin signals induce the physiological changes required for short-day immune responses, perhaps via interactions among hormones downstream from melatonin, such as cortisol and leptin.

In addition to their effects on immune function, corticosteroids can dramatically affect behavior, particularly behaviors associated with reproduction. Generally, stress responses are up- and down-regulated across seasons, but the way in which this happens depends on the social and physical environments in which species live. For instance, songbirds living at high latitudes are thought to mount weak corticosterone responses to stress because the abandonment of offspring that it might lead to would be maladaptive given that these species typically only have one opportunity per year to breed. In the tropics, however, corticosterone–behavior relationships may be different because reproductive efforts are generally less constrained by time.

Considered together, both the incidence and responses to stressors vary on a seasonal basis. The environmental regulation of seasonal changes in many traits, including reproduction, metabolism, and immunity, is primarily mediated by photoperiod. From a physiological prospective, the pineal hormone melatonin appears to coordinate seasonal adjustments in stress responses including changes in reproductive, metabolic, and immune function. To what extent the immune-enhancing effects of melatonin are unique to seasonally breeding rodents and whether it is a generalized feature of seasonal adjustments in stress responses among humans remain largely unspecified. Although physiological responses are important mediators of seasonal and photoperiodic changes in stress responses, behavioral alterations might also have an important role in reducing their energetic costs. The careful integration of the behavioral and physiological mechanisms underlying the seasonality of stress responsiveness at both ultimate and proximate levels should provide important and novel insights into the interaction among seasonal environmental factors, stressors, immune function, and the pattern of diseases and mortality. To date, most efforts have not advanced much beyond describing the seasonal changes that occur in responses to stressors. The next step is to identify the cellular and molecular mechanisms that mediate the effects of season and photoperiod on stress responsiveness and link variability in these mechanisms to fitness.

Evidence for Seasonal Glucocorticoid Rhythms
Mechanisms Regulating Annual Rhythms of
Glucocorticoids
Why Do Seasonal Glucocorticoid Rhythms Exist?
Adaptive Significance

Glossary

<i>Basal glucocorticoids</i>	Plasma concentrations of glucocorticoids in the absence of a stressor.
<i>Corticotropin-releasing hormone (CRH)</i>	Hormone released by the hypothalamus.
<i>Glucocorticoid-binding globulin (CBG)</i>	Proteins in the plasma that bind glucocorticoids.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The neuroendocrine pathway leading from the brain to the adrenals that culminates in glucocorticoid release.
<i>Permissive effect</i>	An indirect effect whereby a hormone indirectly allows another system to work better.
<i>Stressor</i>	A stimulus that elicits a release of glucocorticoids.

Evidence for Seasonal Glucocorticoid Rhythms

Glucocorticoid secretion is often considered an obligatory response to stressors. In a laboratory setting, stressors applied in similar circadian, developmental, and psychological contexts within the same species produce remarkably consistent magnitudes of glucocorticoid secretion. Recent evidence, however, indicates that glucocorticoid release is modulated seasonally in the majority of free-living species that have been studied to date. In other words, the magnitudes of both basal and stress-induced glucocorticoid concentrations vary throughout the year. An example, data for white-crowned sparrows (*Zonotrichia leucophrys*), is presented in [Figure 1](#).

Many recent studies have measured glucocorticoids in free-living wild animals by directly sampling from freshly caught individuals. Plasma samples

collected within a few minutes of capture are assumed to reflect prestress glucocorticoid concentrations because glucocorticoids start to increase 2–3 min after initiation of a stressor. Stress-induced glucocorticoid concentrations then reflect the animal's response to capture, handling, captivity, etc. and are assumed to be a measure of the hypothalamic-pituitary-adrenal (HPA) axis's ability to respond to a stressor.

These studies provide clear evidence that a majority of reptile, amphibian, avian, and mammal species seasonally modulate glucocorticoid concentrations. Males and females sometimes differ in whether they show seasonal rhythms, and occasionally a species will show a seasonal rhythm in basal but not stress-induced glucocorticoid concentrations (or vice versa). However, approximately 90% of all species that have been studied have at least one sex with a seasonal rhythm of glucocorticoid release.

The evidence for an annual glucocorticoid rhythm is generally much stronger for basal concentrations, primarily because more studies have focused on this time point. Furthermore, avian species often show a seasonal rhythm in basal but not stress-induced glucocorticoid concentrations, suggesting that basal and stress-induced glucocorticoid concentrations are regulated differently. Laboratory studies show that basal and stress-induced glucocorticoids have different regulatory mechanisms and serve different physiological functions that are mediated by separate receptors. It is not surprising, therefore, that the HPA axis might be regulated differently under basal and stress conditions, but these regulatory pathways can be further dissociated into different annual cycles.

Of those species that do show a seasonal rhythm, the seasonal peak is usually during the breeding period. There are three notable exceptions. First, the most robust rhythm in birds is a nadir during the prebasic molt when they replace their feathers. This is thought to protect the bird from the protein catabolism effects of glucocorticoids during the protein mobilization of feather replacement. Second, three desert-breeding birds show a seasonal glucocorticoid peak during the rainy season rather than the breeding period, suggesting that seasonal rhythms can be timed to environmental cues as well as seasonal physiological cues. Third, even though most mammal species show a seasonal rhythm, there is no consensus season when mammals tend to have elevated glucocorticoid concentrations.

The capacity of glucocorticoid-binding globulins (CBGs) has also been found to vary seasonally and

Figure 1 Seasonal rhythm of baseline and stress-induced corticosterone from white-crowned sparrows. Reprinted from Romero, L. M. (2002). Seasonal changes in plasma glucocorticoid concentrations in free-living vertebrates. *General and Comparative Endocrinology* 128, 1–24 with permission from Elsevier.

to be regulated by gonadal testosterone. Because only free steroid is generally considered to be available for diffusion into tissues, free steroid concentrations may be more biologically relevant than total steroid concentrations. When total and free steroid concentrations are compared, the seasonal rhythm in total glucocorticoids often changes or disappears entirely.

Many wild species held in long-term captivity also show seasonal rhythms, but these rhythms do not always match what is found in free-living animals. This likely reflects that both domestication and captivity alter HPA axis function in ways that are different for each species, making it difficult, if not impossible, to ascertain natural annual variation from these populations.

Mechanisms Regulating Annual Rhythms of Glucocorticoids

Progress is just beginning in understanding how HPA axis function is regulated seasonally. What induces these changes, be it photoperiod, temperature, food availability, etc., is currently unknown. Plasma glucocorticoid concentrations often are correlated with adrenal mass, and early studies showed increases in adrenal mass during breeding. Consequently, the ability of adrenal tissue to respond to adrenocorticotrophic hormone (ACTH) changes seasonally. A few studies in birds indicate that there are multiple regulatory

points in the HPA axis. Some species seasonally regulate glucocorticoid release from the adrenal, others seasonally regulate ACTH release from the pituitary, and still others regulate CRH and arginine vasotocin (the avian congener of arginine vasopressin) release from the hypothalamus. These regulatory control points may be related to how sensitive each species is to adverse environmental conditions.

Glucocorticoids also interact with the gonadal system. Although glucocorticoids inhibit gonadal hormone release, exogenous testosterone elevates glucocorticoids in free-living birds. This suggests a complex interaction between the gonadal and adrenal systems, with glucocorticoids downregulating gonadal androgen release concurrent with gonadal androgens elevating glucocorticoid release. Gonadal androgens, therefore, could potentially be an important physiological regulator of seasonal glucocorticoid rhythms.

Why Do Seasonal Glucocorticoid Rhythms Exist?

Modulation of glucocorticoid release presents an interesting paradox: if glucocorticoid release is so important for survival, then how do animals survive stressors at certain times of the year when they essentially fail to release glucocorticoids? There have been three major hypotheses proposed to explain seasonal glucocorticoid rhythms.

Energy Mobilization Hypothesis

The energy mobilization hypothesis focuses on the metabolic effects of glucocorticoids. Glucocorticoids play an important role in energy mobilization, especially during stress, so glucocorticoid concentrations should be highest during energetically costly times of the year. According to this hypothesis, high glucocorticoid concentrations during breeding result from breeding exerting the highest energetic demands during the year. Females of many species, for example, expend substantial energy during breeding, and breeding males of many species have increased energy costs associated with testosterone and territorial defense. Moreover, increased energy mobilization could explain seasonal peaks during nonbreeding periods if these periods are more energetically costly than breeding.

Two examples, however, mammalian hibernation and avian molt, highlight the insufficiency of the energy mobilization hypothesis in providing a universal explanation for seasonal glucocorticoid rhythms. Hibernating mammals require dramatically increased fat stores to survive the winter, but it is not clear that these energy requirements are greater or less than lactation. Second, feather replacement during molt in birds requires substantial energy expenditure, yet this period is the nadir of the annual rhythm. The energy mobilization hypothesis can be a powerful explanatory mechanism for certain species during some times of the year, but it clearly is insufficient to fully explain seasonal glucocorticoid rhythms.

Behavior Hypothesis

The behavior hypothesis focuses on the behavioral effects of glucocorticoids. It posits that annual glucocorticoid rhythms result from different requirements for expressing (or not expressing) glucocorticoid-mediated behaviors at different times of the year. For example, an important glucocorticoid-mediated behavior in wild animals might be fleeing an area and relocating during storms. This may be an excellent strategy for most of the year, but could be catastrophic for an individual's overall fitness when relocation requires abandoning young. Consequently, the behavior hypothesis suggests that the need to seasonally regulate the expression of those behaviors drives glucocorticoid rhythms.

The behavior hypothesis, however, does not fit a more general annual rhythm in glucocorticoid concentrations. Glucocorticoid concentrations are highest in most species during breeding, exactly when glucocorticoid concentrations should be lowest if seasonal glucocorticoid rhythms were primarily to regulate the behavioral consequences of glucocorticoid release.

Consequently, this hypothesis may be useful in explaining modulation of glucocorticoid concentrations within a single season, but not across seasons.

Preparative Hypothesis

The preparative hypothesis focuses on the coordinating aspects of glucocorticoid physiology and posits that seasonal rhythms in glucocorticoid concentrations serve to modulate the priming of other stress pathways during periods with different potential exposure to stressors. Glucocorticoids are only one part of the stress response. Other hormones (especially epinephrine and norepinephrine), neurotransmitters (e.g., 5-HT, CRH), opioid peptides, and cytokines (e.g., IL-6), as well as other brain functions, exert their effects rapidly with the onset of stress without involving the pituitary or adrenals. However, glucocorticoids have a permissive effect on many of these systems and thereby facilitate better performance under stress. Higher basal glucocorticoid concentrations may augment the priming effects on these systems in preparation for further stressors. This is the traditional explanation for timing the circadian peak for the beginning of the active period. These permissive effects may help prepare the organism for subsequent stress responses.

If the preparative hypothesis is correct, higher glucocorticoid concentrations should coincide with seasons in which predictable stressors are more likely. The available data fit this prediction moderately well. The risk of exposure to many stressors in wild animals likely varies seasonally. During the breeding season, for example, predation risk may increase when caring for young; competition for mates, with the risk of frequent fights, increases; and disease may become more prevalent when breeding individuals congregate. Consequently, glucocorticoid concentrations may vary seasonally in order to mediate changes in preparedness in the nonglucocorticoid pathways of the stress response. However, the existence of predictable seasonal increases in stressor risk has not yet been demonstrated.

Adaptive Significance

Proper concentrations of glucocorticoids seem crucial for survival. Too little can result in even mild stressors killing animals, but too much can lead to suppressed gonadal and immune function and ultimately disease. Consequently, a balance must be struck between needing glucocorticoids to survive stressors and modulating glucocorticoid secretion to prevent deleterious exposures. What is becoming clear is that there is a seasonal rhythm in what is the

right amount of glucocorticoids. Understanding why the right amount changes seasonally will help us understand why glucocorticoids are released during stress and how they help animals survive. The three explanatory hypotheses presented earlier are derived from different aspects of glucocorticoid physiology. The energy mobilization hypothesis emphasizes glucocorticoid's metabolic effects; the behavior hypothesis emphasizes the desired acute behavioral effects of glucocorticoids; and the preparative hypothesis emphasizes the regulatory role that glucocorticoids have in other stress systems. Integrating these hypotheses into a cohesive physiology will provide the foundation for understanding how elevated glucocorticoid concentrations aid in survival.

Glossary

Catecholamines

Adrenaline and noradrenaline are catecholamines. Neurotransmitters of the sympathetic nervous system (noradrenaline) and the adrenal medulla (adrenaline), they rapidly prepare the body for flight or fight in response to a stress. This is achieved mainly by adrenaline or noradrenaline stimulation of glucose release from the liver, increased heart rate, and redistribution of the blood circulation (by tissue-selective vasomotor control) from nonessential (e.g., the gut) to essential organs such as the brain, heart, and skeletal muscles.

Chemical neurotransmitter

A compound synthesized and released by a nerve cell (neuron) that activates or inhibits another neuron or other type of excitable target cell such as muscle.

<i>Chromagranins</i>	A class of acidic proteins present in large secretory granules (vesicles) in neuroendocrine tissues and neuroendocrine-derived tumors. Chromagranins were first identified in the chromaffin cells of the adrenal medulla, sympathetic nerves, and the pituitary gland. One of the chromagranins, secretogranin II, is the precursor of secretoneurin, a neuropeptide with a wide distribution in brain through all vertebrate phyla.
<i>Endocrine glands</i>	Glands that secrete signaling molecules, termed hormones, into the bloodstream, which transports the hormones to their target organs and tissues, where they exert their effects.
<i>Exocrine glands</i>	Glands that secrete to the outside of the body (i.e., into the gut, nasopharynx, bronchial tree, genitourinary system, and skin) as opposed to endocrine glands, which secrete hormones into the bloodstream. The acinar cells of the pancreas, which secrete gut enzymes, are key examples of exocrine cells in the context of this topic.
<i>Exocytosis</i>	The release of a secretory product, such as neurotransmitters, in packets or quanta. The secretory products are packaged by the Golgi apparatus of the cell in membrane-bound vesicles; exocytosis involves fusion of the vesicular membrane with the cell membrane, resulting in the release of the quantum of product inside the vesicle. This is thought to be the main mechanism of secretion in most secretory cells, including neurons.
<i>Ligand</i>	A molecule that binds or bonds specifically to another substance/compound – in biology, usually a receptor.
<i>Neurohormone</i>	A compound synthesized and released by a nerve cell that reaches its target by transport in special vessels, such as the hypothalamo-hypophyseal vessels in the case of the hypothalamic-pituitary system, or the systemic circulation for peptides such as oxytocin and vasopressin whose targets are in the periphery. Most, but not all, neurohormones are peptides.
<i>SNAP-25</i>	Synaptosome-associated protein of 25 kDa; one of the SNARE proteins involved in calcium-regulated exocytosis.
<i>SNARE proteins</i>	Soluble N-ethylmaleimide-sensitive factor attachment protein receptors; involved in calcium regulated exocytosis.
<i>Stimulus secretion coupling</i>	The link between a stimulus, usually membrane depolarization (axon potentials in the case of nerve cells) under physiological conditions, and the release of a neurotransmitter or neurohormone.

Principles

A secretagogue is an agent that promotes the secretion of hormones, neurohormones, chemical neurotransmitters, enzymes, or other compounds synthesized and secreted by cells. The selectivity or specificity of a secretagogue is determined by the structure of the secretagogue and that of its receptors on or within the cell. Secretagogues may be endogenous biological agents natural to the animal, exogenous compounds obtained from plants, or artificially synthesized pharmacological agents. The activity of exogenous secretagogues is thought to be due to the fact that the agent, by virtue of its chemistry and conformation, is capable of activating receptors specific to an endogenous secretagogue. There are numerous examples of this type of pharmacological mimicry: for example, acetylcholine (endogenous) and nicotine or muscarine (plant derived), opiates (plant derived), and the endogenous opioids – enkephalins and endorphins. The different classes of receptors that mediate secretagogue action are outlined later in the article.

Some secretagogues are nonspecific and will stimulate the release of most secretory substances. The most widely known and commonly used (experimentally) nonspecific secretagogue is a high concentration of extracellular potassium ions. High extracellular potassium concentrations trigger secretion by depolarizing the cell membrane, which induces a massive increase in intracellular calcium ions. Studies with calcium ionophores (compounds that induce calcium influx into cells) and calcium channel modulators in adrenaline-secreting chromaffin cells suggest that it is the rate of calcium ion influx rather than the absolute level of intracellular calcium ion reached that determines the amount of catecholamine released. Secretagogue-induced depolarization of cell membranes is associated with the release of neurotransmitters, neurohormones, some pancreatic and salivary gland enzymes, and the pancreatic hormone insulin. The coupling of stimulus-induced membrane depolarization with secretion is termed stimulus–secretion coupling, a term coined by W. W. Douglas based on his work on the neurohypophysis and the adrenal medulla.

Secretagogues Involved in the Neuroendocrine Response to Stress

Several secretagogues are involved in organizing the biological response to stress. Thus, stress, most frequently generated by an event recognized by the senses as dangerous or potentially dangerous, activates neuronal systems in higher brain centers that activate the main components of the limbic system, which include the hippocampus, amygdala, and

hypothalamus. This activation and the transmission of signals between nerve cells (neurons) involve the release of chemical neurotransmitters at nerve junctions (synapses). Nerve impulses generated as a consequence of stress activation of higher brain centers and the limbic system are transmitted to the paraventricular nuclei (PVN) of the hypothalamus, the major stress nuclei of the brain. These nuclei comprise neurons that synthesize and secrete corticotropin-releasing hormone-41 (CRH-41) and arginine vasopressin (AVP) and project to the median eminence of the hypothalamus, where they terminate on the primary plexus of the hypophyseal portal vessels. Released from PVN terminals in the median eminence and transported to the anterior pituitary gland by the hypophyseal portal vessels, CRH-41 and AVP act synergistically to stimulate the release of adrenocorticotropin (ACTH) into the systemic circulation. The PVN neurons, therefore, constitute the final common pathway neurons of the central neuroendocrine stress control system. Final common pathway neurons was a term first used by Sherrington to describe the alpha motor neurons of the spinal cord that project to and control skeletal muscle activity.

In humans and rodents, CRH-41 is the main secretagogue for ACTH release; its action is potentiated by AVP. In sheep, the situation is reversed, with AVP being the main ACTH secretagogue and CRH-41 potentiating the action of AVP. In addition to these ACTH-releasing factors, there is experimental evidence that under certain conditions the brain may inhibit ACTH release. A likely candidate for an ACTH-inhibiting factor is the cardiac hormone atrial natriuretic peptide (ANP), which is also synthesized in PVN neurons and released into hypophyseal portal blood.

Transported by the circulation to the adrenal glands, ACTH is the main secretagogue for stimulating the release of adrenal corticosteroids, and especially the glucocorticoids, cortisol in humans and corticosterone in rodents. Under certain situations, steroids can be secretagogues. Thus, estrogen, in its positive feedback mode for gonadotropin release, induces the release of gonadotropin-releasing hormone and prolactin, albeit possibly by indirect actions. Estrogen can also potentiate compound 48/80- or substance P-induced release of serotonin and histamine from mast cells. Glucocorticoids are potent inhibitors of ACTH release; this action is exerted directly on the anterior pituitary gland, where glucocorticoids inhibit the action of CRH-41 and AVP, as well as on the hypothalamus, where they inhibit CRH-41 and AVP release. This inhibitory effect of glucocorticoids is the basis for their negative feedback control of ACTH release. Whether corticosteroids are secretagogues is

not known; however, by exerting pronounced effects on protein synthesis and enzyme activity in nerve and other cells, corticosteroids modulate the action of secretagogues.

In addition to what might be called the classical secretagogues of the brain-pituitary-adrenal system, other secretagogues implicated in the control of stress-induced glucocorticoid secretion include urocortin (a homolog of CRH-41), angiotensin II, and cytokines such as tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β). TNF- α and IL-1 β both stimulate ACTH release and are two of several secretagogues that link the immune and neuroendocrine defense systems. Extreme stress, such as that produced by multiple trauma or septic shock, results in a paradoxical decrease of the secretion of ACTH in the presence of increased cortisol secretion. It is postulated that this paradox may be brought about by the inhibition of ACTH secretion by ANP and by the direct adrenocortical stimulation of glucocorticoid secretion by the peptide endothelin-1.

Multiple Secretagogues in Other Systems: Exemplified by Growth Hormone Secretion

The existence of more than one secretagogue for pituitary hormones is not confined to ACTH. Thus, growth hormone (GH) release is regulated by two hypothalamic peptides or neurohormones: GH-releasing hormone, which stimulates GH release, and somatostatin, which inhibits GH release. Ghrelin, a peptide secreted by the stomach, is also an endogenous ligand for the GH secretagogue receptor. Ghrelin appears to be present also in the hypothalamus, but its precise mechanism of action and interactions with GH-releasing hormone and somatostatin needs to be elucidated. Finally, GH release is also induced by increased plasma concentrations of certain amino acids, such as arginine and lysine (which can therefore be regarded as GH secretagogues). However, while arginine (administered intravenously) is used as a provocative test of GH secretion in human subjects, there appears to be no robust evidence that amino acids administered orally stimulate detectable sustained GH release.

Sympathetic System: Role in Fight or Flight and Model for Exocytosis

The sympathetic component of the autonomic nervous system and the adrenal medulla play an equally important role in the stress response, especially in the acute phase when autonomic activation prepares the animal for fight or flight. That is, in response to stress, the brain through the hypothalamus and hindbrain

centers activates the sympathetic nervous system, which, through the release of noradrenaline at sympathetic nerve terminals and adrenaline from the adrenal medulla, stimulates several physiological changes that include an increase in heart rate and blood pressure and the rapid mobilization of glucose production by the liver.

Stimulation of adrenaline secretion from the adrenal medulla by the preganglionic secretagogue acetylcholine has been used extensively as a model for the investigation of secretagogue action and stimulus-secretion coupling. Based on the seminal electrophysiological studies of Bernard Katz and associates and confirmed by ultrastructural (electron microscopical) findings, it has long been accepted that stimulus-secretion coupling results in the release of neurotransmitters, hormones, and enzymes by way of exocytosis. Work on the adrenal medulla and sympathetic nerves proved important for elucidating the mechanism of exocytosis and the recycling and reuse of vesicular membranes, the characterization of the chromagrins, and the identification of peptides involved in exocytosis such as syntaxin, SNAP-25 and L- and N-type calcium channels. In brief, secretory vesicles formed at the trans-Golgi network of neuroendocrine and endocrine cells undergo translocation, docking, and priming before they are ready to fuse with the plasma membrane and release their secretory product into the extracellular space. This process, termed regulated exocytosis, is controlled by Ca^{2+} (using synaptotagmin) and is mediated by SNARE proteins. For details about this and vesicle priming, depriming and cell-membrane fusion see Stojilkovic (2005).

Receptors and Intracellular Signaling Cascades

There are two broad classes of receptors – cell surface and nuclear. Located intracellularly, the nuclear receptor superfamily binds steroid (e.g., cortisol, corticosterone, aldosterone, estradiol, testosterone) and thyroid hormones, derivatives of vitamins A and D, and xenobiotics. Cell surface receptors are composed of the following classes (examples of ligands):

1. Ligand-gated ion channels (e.g., nicotinic acetylcholine receptor)
2. Receptor tyrosine kinases (e.g., insulin, insulin-like growth factor, epidermal growth factor)
3. Receptor serine/threonine kinases (e.g., activin, inhibins)
4. Receptor guanylate cyclase (e.g., atrial natriuretic peptide)

5. G-protein-coupled receptor superfamily (e.g., adrenergic agents, muscarinic acetylcholine agents, peptide hormones and neurohormones, glycoproteins, glucagon, parathyroid hormone)
6. Cytokine receptors (e.g., growth hormone, prolactin, leptin)

With the exception of glucocorticoids, cell surface receptors are the targets of all the secretagogues involved in the neuroendocrine response to stress. Thus, CRH-41, vasopressin, ACTH, adrenaline, and noradrenaline all bind to specific G protein-coupled receptors, while ANP binds to guanylate cyclase receptors. Acetylcholine, the preganglionic secretagogue that triggers adrenaline release from the adrenal medulla, acts by way of nicotinic acetylcholine receptors on adrenal medullary cells.

Secretion induced by ligand activation of non-voltage-dependent cell surface receptors is triggered by one of a series of intracellular signaling cascades, the most well known of which are the adenylyl cyclase, phosphatidyl inositol, and kinase systems. As indicated previously, secretagogue-induced secretion involves a rapid increase in the intracellular concentrations of calcium ions, triggered either by effects on the cell surface calcium channels in the case of voltage-dependent receptors, or by the intracellular signaling cascades in the case of non-voltage-dependent receptors. In addition to stimulating secretion, activation of cell surface receptors frequently results in gene transcription that can lead to synthesis of secretory product or a key enzyme involved in the synthesis of secretory product. The latter is exemplified by the fact that acetylcholine, which induces the secretion of adrenaline from the adrenal medulla and noradrenaline from postganglionic neurons of the sympathetic system, also induces the synthesis of tyrosine hydroxylase, the rate-limiting enzyme for the synthesis of noradrenaline and adrenaline. This action of acetylcholine appears to be mediated by both nicotinic voltage-dependent receptors and muscarinic G protein-coupled receptors.

Conclusion

The mechanism of action of secretagogues is the subject of intensive research and is one of the major themes of modern molecular biology and molecular pharmacology. Calcium ions play a pivotal role in the action of secretagogue-induced secretion by exocytosis. Although a good deal is known about secretagogue action, a more rigorously defined understanding is likely to emerge from modern molecular genetic and microphysiological approaches.

Serotonin and the Selective Serotonin Reuptake Inhibitors
Stress and the Brain

Stress and Serotonin

Antidepressants, SSRIs, and Stress Responses

Glossary

<i>Brain-derived neurotrophic factor (BDNF)</i>	A brain peptide that enhances growth of neurons.
<i>Hippocampus</i>	A brain structure vital for learning and memory.
<i>Selective serotonin reuptake inhibitors (SSRIs)</i>	A class of antidepressants that have the dominant initial biological effect of increasing serotonin in the synaptic cleft.
<i>Serotonin</i>	A neurotransmitter that is involved in the regulation of mood, anxiety, and stress responsiveness, among other effects.

Serotonin and the Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are the dominant class of antidepressants prescribed in the Western world. Although they are not more effective than other classes of antidepressants, their ease of use (most patients show optimal benefit from one daily dose of any of the SSRIs), their relatively benign side effect profile, and the extraordinary marketing campaigns by the pharmaceutical manufacturers of the individual agents have made them the most commonly prescribed antidepressants and among the most commonly prescribed agents in all of medicine.

All SSRIs share the common trait of blocking the serotonin transporter, the receptor on the presynaptic neuron that regulates the reuptake of serotonin back into the presynaptic neuron. The functional consequence of blocking serotonin reuptake is to allow serotonin to remain in the synaptic cleft longer, thereby enhancing its likelihood of hitting the postsynaptic serotonin receptor. The end result of this is to enhance serotonin neurotransmission. The strength of serotonin activity at serotonin receptors is

inversely proportional to the number of serotonin transporter molecules present at the presynaptic membrane. Although the mechanism by which SSRIs ameliorate depression is far more complex than this, the initial enhancement of serotonergic function by reuptake blockade is generally thought to be the first step in a cascade of biological effects.

Although originally released and marketed as treatments for depression, SSRIs have now been demonstrated to be effective in a wide variety of psychiatric disorders, including panic disorder, social anxiety disorder, obsessive-compulsive disorder, generalized anxiety disorder, posttraumatic stress disorder (PTSD), and some of the symptoms of certain personality disorders. Thus, these powerful serotonin enhancers seem to be effective treatments in a wide variety of mood and anxiety disorders. Many, but not all, of these disorders can be triggered or exacerbated by acute or chronic stress. For some individuals – specifically those whose depressive episodes are triggered by acute or chronic stressful life events – depression can be described as the end product of failed adaptation to chronic emotional stress. Because of the overlap among anxiety disorders, depression, and stress, the remainder of this article reviews all three, even though, of course, these are similar but not identical constructs or clinical conditions.

Stress and the Brain

Stress alters the brain in a variety of ways. Two of these stress-related effects – decreases in hippocampal volume and the diminishing of the activity of a brain peptide, brain-derived neurotrophic factor (BDNF) – are highly relevant in understanding the potential effects of antidepressants and SSRIs, in particular in their altering responses to stress.

A decrease in the volume of the hippocampus, the brain structure vital for learning and memory, is among the most consistent consequences of stress. In rodents, experimental chronic stress causes the loss of hippocampal neurons. Similar findings have been demonstrated in humans suffering from depression and in other stress-related psychiatric disorders such as PTSD. Lower hippocampal volumes in depressed patients compared with normal people are seen bilaterally, although this finding is more consistent on the left versus right hippocampus. Similar findings are seen with PTSD, even in those patients not suffering from comorbid depression. In addition, in two studies, the reduction in hippocampal volume

correlated with the length of the depressive illness. It is as yet unclear whether these changes in actual brain structure seen with stress versus psychiatric disorders such as depression or PTSDs are similar or identical.

The second important stress-related effect on brain function is in the decreasing activity of the brain peptide BDNF. BDNF plays a major role in the survival, growth, and protection of neurons, both in the central and the peripheral nervous systems. The role of BDNF in neuronal function continues into adult life; thus, BDNF should be considered as playing an ongoing regulatory role for optimal neuronal function in youngsters and adults. Normally, neurons are rewired and shaped (with the sprouting of dendrites, called dendritic arborization) throughout adult life. BDNF seems integrally involved with this process. In addition, the production of new neurons in adults, called neurogenesis, seems also to be regulated in part by BDNF. Of note, BDNF shows the greatest expression in the hippocampus, the brain region most consistently demonstrated to show morphological changes in stress and depression.

In animals, a variety of stressors (such as forced immobilization in rats or learned helplessness following exposure to inescapable shock) consistently cause a dramatic reduction in BDNF expression in the hippocampus. There is some evidence that the prolonged glucocorticoid secretion (see **Glucocorticoids, Effects of Stress on, Glucocorticoids, Role in Stress**) that is consistently observed in association with severe stress may mediate some of the effects of stress and depression on decreased BDNF function.

Human studies of BDNF are more difficult to obtain because direct measurements of brain are not possible to obtain and the relationship between blood and brain levels of BDNF is still uncertain. Nonetheless, in one study, serum BDNF levels in depressed patients were reported to be lower than those seen in normal controls. In addition, in another study, serum BDNF levels correlated inversely with depression rating scale scores.

Stress and Serotonin

Central nervous system responses to stress are mediated by multiple neurotransmitter systems (see **Primates: Rearing and Effects of Stress on Primate CNS Function, Stress and CNS Arousal; Genomic Contributions**). Consistent evidence suggests that the serotonin system plays an important role in the brain's response to stress, thereby further suggesting that modifying serotonergic function may alter responses to stress. In animals, low serotonin is associated with increased sensitivity to environmental cues and greater responsiveness to threat. In humans,

this implies that individuals with low serotonin may be more easily traumatized by stressful life events (or have a lower threshold for showing the effects of traumatic events) than those with higher baseline serotonin levels.

The likelihood of stress triggering depressive symptoms and disorders seems to be moderated in part by different profiles of the gene that helps regulate the serotonin transporter (i.e., the receptor that regulates the reuptake of serotonin into the presynaptic neuron). In a seminal study, young adults with either one or two copies of the short allele of the gene that helps regulate the serotonin transporter were more likely to become depressed (as measured by either symptoms or disorders) but only when stressed by life events such as employment problems, health issues, housing or relationship issues, and so forth. In addition, childhood maltreatment similarly predicted adult depression only among those with the short allele of the serotonin transporter gene. The implication of this study is that responses to stress and the vulnerability to becoming depressed due to the stress can be predicted by a genetic measure of serotonin function.

Similarly findings can be seen in stressed non-human primates. Infant macaque monkeys raised in peer groups were compared to those reared with their mothers. (Lack of normal mothering can be considered an early stress or trauma in both nonhuman primates and in humans.) The biological marker for stress was adrenocorticotrophic hormone (ACTH) and cortisol levels, both of which are altered in stressful conditions (see **Adrenocorticotrophic Hormone (ACTH), Hypocortisolism and Stress**). Monkeys with the short allele of the serotonin transporter gene showed greater alterations in ACTH and cortisol levels during separation from mothers than those with the longer allele. Thus, these experimental results in monkeys are entirely consistent with the results seen in young adult humans.

Another clue that serotonin may be intimately linked to the effects of stress was demonstrated in a study of infant rhesus monkeys who were raised in mother-reared versus peer-reared conditions. Early maternal deprivation was associated with decreased serotonin metabolites in the cerebrospinal fluid (CSF), a marker for serotonin function in the central nervous system. Furthermore, this decrease in serotonergic function stayed stably lower for the 5 months of the study, implying a potentially long-term effect of stress and trauma on brain serotonin activity.

The regulation of BDNF by specific neurotransmitters is assuredly complex. However, there is some evidence that serotonin plays a role in neurogenesis and may, therefore, be linked with BDNF function. As an example, experimental lesions of the serotonin

system have been shown to decrease neurogenesis in animals. Serotonin agonists increase neurogenesis, an effect blocked by serotonin antagonists. Thus, medications that alter serotonin function, such as SSRIs, can theoretically be expected to increase neurogenesis. Not only do antidepressants enhance BDNF function, but BDNF has been reported to be a potent neurotrophic factor for norepinephrine and serotonin neurons. Thus, if these preliminary data hold true, the relationship between antidepressants and BDNF is best described as reciprocal or bidirectional.

Antidepressants, SSRIs, and Stress Responses

Given that markers of stress and stress-related effects on brain function include both decreasing hippocampal size and diminishing BDNF activity, antidepressants might exert therapeutic effects by preventing or reversing both these effects. Evidence supports both these possibilities.

Antidepressants have been demonstrated to increase neurogenesis in rats. Of note, the antidepressant classes that have shown these positive effects include SSRIs, tricyclic antidepressants, and monoamine oxidase (MAO) inhibitors. The positive effects on neuronal remodeling and neurogenesis seem to require 2–4 weeks of treatment, similar to the time frame of clinical response to these agents in depressed individuals. Electroconvulsive therapy (ECT), with its well-documented antidepressant effects, also increases BDNF expression, as does transcranial magnetic stimulation (TMS), a more recently described antidepressant treatment. The mood stabilizers lithium and valproate, used primarily in the treatment of bipolar disorder, show similar effects. Of note, psychotropic agents from other classes such as antipsychotics and opiates are not associated with increased BDNF activity, implying that the effects may be relatively specific to agents with antidepressant or mood-stabilizing effects.

In addition, as hypothesized, antidepressants also reverse the decreased neurogenesis seen in association with chronic stress and can block this effect of chronic stress when administered preventively. This effect, seen in animal experiments, is entirely consistent with the human evidence that antidepressants administered on a long-term maintenance basis can prevent depressive episodes in individuals vulnerable to them.

It must be acknowledged, however, that even in SSRI studies not all the data demonstrate the salutary effects of these agents on increasing BDNF, neurogenesis, or reversing hippocampal atrophy. In some studies, the expected positive effect is simply not

observed. In other rodent studies, the behavioral effects of antidepressants were seen but the enhancement of BDNF function was not, implying that BDNF enhancement was not necessary for the antidepressant behavioral effects.

Interestingly, one factor other than antidepressants that can increase neurogenesis/cellular remodeling in the hippocampus is exercise. In animals, exercise plus antidepressants enhanced BDNF function more than antidepressants. This may partially explain the mild antidepressant effect of aerobic exercise in humans.

Similar observations supporting the role of SSRIs in reversing stress-induced changes in the central nervous system have been made with anxiety models in animals and anxiety disorders in humans. Maternally deprived animals with increased acoustic startle responses and enhanced activity of the hypothalamic-pituitary-adrenal (HPA) axis showed a reversal of these effects with the SSRI paroxetine over a 3- to 4-week time frame (similar to the expected time to clinical effect in anxiety disorders in humans.) In humans, in one study, paroxetine both improved symptoms of PTSD but also enhanced cognitive performance and increased hippocampal volume.

Although all antidepressants may ultimately demonstrate the type of positive effect on reversing and/or preventing stress responses, there may be some differences across antidepressant classes. As one example, although some studies are positive, there are a number of other studies suggesting that tricyclic antidepressants do not consistently increase BDNF, as do other antidepressant classes such as SSRIs.

Consistent with the notion that there may be differences across antidepressant classes in modulating stress responses, a recent study compared the effect of an SSRI to reboxetine, an antidepressant that enhances norepinephrine (but not serotonin) in normal individuals responding to positive and negative images. Although both antidepressants diminished responses to negative emotional material, only the SSRI (citalopram) abolished the increased startle response in the context of negative affective images. The implication of this observation is that antidepressants with strong effects on serotonin, such as SSRIs, may be able to selectively block reactions to negative affective situations that may therefore enhance individuals' capacity to resist the negative effects of stress by blunting the affective and biological response to it.

Because virtually all the research discussed in this chapter is recent, only further studies, many of which are ongoing, will establish how consistently antidepressants reverse stress-related brain changes and whether these effects are common to all antidepressant classes and not just to SSRIs.

The Concept of Self-Esteem

Stress and Personality

Stress and Self-Esteem

Conclusion

Glossary

Emotional inhibition

The inhibition of the expression of experienced emotion.

Factor analysis

A statistical technique for identifying clusters of related items (factors) in questionnaires and for identifying redundant items in preliminary questionnaires. Deciding how many factors to extract is usually based on either an eigenvalue-1 criterion or a scree test,

Hypothalamic-pituitary-adrenal (HPA) axis

with the latter providing the more conservative estimate.

The link between the hypothalamus, the pituitary, and the adrenal cortex and medulla. The activation of the adrenal medulla in response to demands, including perceived stress, results in elevated secretion of catecholamines such as epinephrine and norepinephrine. Elevated secretion of adrenal corticosteroids such as cortisol also occurs in these circumstances via the release of corticotrophic hormones from the pituitary gland.

Neuroticism

The tendency toward emotional lability or emotional sensitivity.

Personality traits

Enduring, stable predispositions to behave in a particular way.

Rumination

The tendency to persist in thinking about emotionally upsetting events that have happened in the past or might occur in the future; also called emotional rehearsal.

Self-esteem

An evaluative measure of how individuals feel about themselves; includes perceived attractiveness, competence, and confidence.

<i>States</i>	Unstable aspects of personality, such as moods, that vary according to circumstances.
<i>Type</i> <i>A behavior pattern</i>	(TABP) Behavior, such as hostile competitiveness and time urgency, that is thought to increase individuals' susceptibility to coronary heart disease.

Self-concept is a central theme in personality psychology. For the purpose of controlled studies, it is usually operationalized as self-esteem, and a number of self-report psychometric scales have been developed to assess the degree to which individuals value themselves. These self-evaluative perceptions are a reflection of the way individuals feel about their attractiveness and their competencies, and the concept of self-esteem has an intuitive logic in the sense that almost everything people do is evaluated in terms of how successful or valued they feel they are.

Self-esteem clearly has important psychological implications, particularly for stress and personality, but the research has been hampered by conceptual and methodological problems. Many of the early definitions were overinclusive, and the assessment of self-esteem has been marred by psychometric shortcomings. However, work over the past 2 decades has begun to address these issues, leading to a clearer and more precise understanding of self-esteem.

The Concept of Self-Esteem

As early as 1890, William James described self-esteem as being dependent on the match between aspirations (which he called pretensions), on the one hand, and achievements or successes, on the other; the greater the discrepancy between aspiration and actual achievement, the lower self-esteem is likely to be. This suggests a constantly changing process, but self-esteem can also be defined as a relatively permanent predisposition or trait. Indeed, James acknowledged that people tend to have a more or less consistent view of their own self-esteem, developed over time and relatively unaffected by circumstance. Other early theories on the self-concept suggested that the opinions of significant others constituted a kind of mirror in which we view and evaluate ourselves. Although this social self-esteem might vary according to the criticism or the praise we receive, these perceptions became generalized to form an enduring composite of self-attitudes.

Recent trends in research on the self have revived the distinction between relatively stable trait self-esteem and unstable state self-esteem and have provided evidence to show that the distinction is empirically meaningful. For example, assessing

self-esteem repeatedly over successive days yields groups with relatively stable or unstable self-esteem. When these two groups are given either positive or negative feedback on their social skills, they differ in their responses, with the unstable high self-esteem subjects generally having more favorable responses to positive feedback but more defensive reactions to negative feedback. The results of these studies suggest that people with unstable high self-esteem are in fact characterized by a poorly developed self-concept and are more reliant on external evaluations and opinions than those with stable high self-esteem.

If the distinction between stable and unstable tendencies were not made, all of these subjects would have had apparently high self-esteem, and the questionnaire responses of the unstable subjects masked an underlying uncertainty and lack of confidence. This approach has been echoed in research on perceived control, which at the extremes of a normal distribution distinguishes between subjects with either an internal or an external locus of control. The former consider their behavior to be a consequence of their own actions, whereas the latter typically attribute events in their lives to luck, chance, or powerful others. However, a further distinction can be drawn between congruent and defensive externals – those who genuinely believe in fate or luck (congruents) and those who say they do in order to protect themselves in the event of failure (defensives). The defensive subjects are identified by their scores on measures of social desirability, which are thought to reflect a desire for approval.

In the context of self-esteem, a similar distinction can be drawn between subjects with high self-esteem and a high need for approval and those with high self-esteem but a low need for approval, based on their scores on social desirability. When these groups are asked to perform ambiguous tasks that allow believable success and failure feedback to be given and are then invited to indicate what they would like their ideal performance to be on a subsequent task, the subjects whose ideal is most diminished by the failure feedback on the analogous task are those with defensive high self-esteem. By contrast, high self-esteem subjects with a low need for approval are unaffected by such experimental manipulations.

More recent research has shown that the degree to which self-esteem is affected by feedback is moderated by other psychological variables, including emotional intelligence (EQ). Self-esteem is positively correlated with measures of EQ, but when individuals with either high or low EQ are exposed to laboratory manipulations that induce negative affect, those with high EQ showed less reduction in self-esteem than those with low EQ.

These effects have been borne out in more naturalistic settings that have incorporated other correlates of self-esteem, such as the degree of perceived support from significant others. A study of distress among cancer patients showed that a perceived lack of social support led to lower self-esteem, which in turn was linked to greater distress. Not surprisingly, self-esteem is also strongly negatively correlated with depression, and a related study of the link between negative marital interactions and depression in arthritis sufferers showed that the relationship was significantly moderated by self-esteem. Conversely, prospective research designs have shown that having social support is associated with high self-esteem, which in turn increases optimism while decreasing depression.

The overall findings confirm that the construct does indeed have two facets: a relatively stable, resilient self-regard, and a more changeable aspect that depends on external circumstances. Although people with genuinely high underlying self-esteem are less affected by a perceived lack of competence in particular situations than those with either low self-esteem or unstable high self-esteem, exposure to self-critical conditions results in diminished self-esteem. An important question raised by these findings is whether self-esteem can systematically be enhanced by targeted training interventions. One study that suggested that it can be involved the random allocation of physically disabled women to two training groups, one of which included a self-esteem enhancement program. The follow-up showed that the women in the experimental group that received the self-esteem training had significantly improved self-esteem as well as lower levels of depression.

However, one of the problems with experiments on self-esteem is the question of reliability. Self-esteem is typically assessed by self-report questionnaires, and it is difficult to ensure that people will respond honestly, particularly where the questions have a personal, evaluative connotation. The problem of response bias is inherent in questionnaire assessment techniques and can only adequately be overcome by using some form of control scale such as social desirability.

Another psychometric problem inherent in scale construction is the distinction between general and multidimensional structure. For example, one of the more widely used self-esteem scales is the 10-item Rosenberg Self-Esteem Inventory. This has the advantage of being extremely brief and easy to administer, but it is usually considered to be unidimensional and it does not break down into different domains of self-esteem. Other popular measures that offer systems for scoring responses into subscales covering areas such as academic, family, and social self-esteem are also thought to represent a single general factor,

despite the breakdown into different domains. By contrast, many of the more recent self-esteem scales are predicated specifically on multidimensional models of self-concept. The subscales within these questionnaires typically cover broad domains of physical, social, and academic self-esteem, and there is evidence to show that the subscales are empirically discriminable. However, the most satisfactory of these models are also hierarchical and include a higher-order general factor. Indeed, when conservative techniques such as scree tests are used for extracting factors rather than an eigenvalue-1 criterion, a single general factor is usually indicated for self-esteem questionnaires.

In principle, higher-order general factors in personality are more likely to be independent of one another than lower-order ones. Neuroticism and extraversion, for example, are postulated as statistically independent dimensions. However, self-esteem correlates significantly negatively with neuroticism and positively with extraversion, and it correlates significantly with a wide range of other personality variables as well. This is perhaps not altogether surprising in view of the degree of item-overlap among them. Neuroticism scales are a case in point. They include items that are explicitly concerned with self-esteem, such as "Are you troubled with feelings of inferiority?" and "Do you worry a lot about your looks?"

Setting aside the effects of item-overlap, it may be that the patterning of these other personality dimensions is, in fact, determined by individual differences in self-esteem – in other words, that self-esteem might represent a highest-order construct. What is clear from the research findings is that self-esteem exerts a powerful influence on behavior, and this can be captured by a compensatory model that formalizes the relationship between self-esteem and other aspects of personality, with particular reference to stress and health.

Stress and Personality

Stress has been defined in a variety of ways, with each definition having important implications for the way in which it is measured. Stimulus definitions, for example, led to the development of life-event scales for assessing stress. These instruments continue to be used, despite widespread evidence that life-event reporting is fundamentally flawed. By contrast, response definitions have often focused on physiological changes, and this has proved to be a particularly useful avenue of research for linking stress and illness. Recent advances in psychoneuroimmunology have shown that sustained activation of the HPA axis following exposure to stress may have deleterious consequences; the elevation in adrenal catecholamines

has a significant impact on cardiovascular function, and there is good evidence for the role of adrenal corticosteroids in compromising immune competence.

However, wide individual differences in stress reactions suggest that physiological response mechanisms alone provide only a partial answer. A number of researchers proposed that aspects of personality might play a significant role, and early work on the concept of hardiness suggested that having an internal locus of control may serve as a buffer against stress. Hardiness is a composite of three dimensions: control, commitment, and challenge. Early research had suggested that hardiness, and particularly the control component, might be important in buffering individuals against stress. Unfortunately, subsequent findings using locus of control to investigate the role of personality in stress and illness have been equivocal, as have findings with other variables such as neuroticism and extraversion.

Locus of control is a dimension of personality, but the stimulus properties of control can also be investigated by manipulating the degree of control available over environmental factors. Pioneering experiments in the context of stress used pairs of monkeys, one having control over shock avoidance (the executive monkey) and a yoked companion monkey that did not. The findings suggested that the executive monkey was more likely than the yoked monkey to develop gastrointestinal lesions through anticipatory stress arousal. However, other researchers obtained the opposite result, and it has been pointed out that the relationship between control and stress is more complex; control tends to be harmful primarily when it involves engaging in active and effortful coping responses. The picture becomes even more complicated when individual differences in perceived control are included; having an internal locus of control has been shown to be associated with a greater susceptibility to stress among subjects who experienced high levels of uncontrollable life events.

In view of the inconclusive findings from research on the role of personality in stress and illness, it has been argued that the personality constructs used in earlier studies were inappropriate because they had not been developed specifically in the context of stress research. A number of scales for assessing aspects of emotional response styles have emerged from stress research programs, and subsequent validation studies of these scales have shown that behavior such as rumination and emotional inhibition is strongly related to physiological indices of stress. Rumination in particular has been shown to prolong heart-rate recovery and corticosteroid secretion, and recent findings have shown a significant link between rumination and suppressed immune function. Other work

has implicated the tendency to inhibit the expression of emotion in a range of physiological response mechanisms, including delayed muscle tension recovery following exposure to stress. Research on emotion control is thus set within the context of adrenomedullary and adrenocortical response mechanisms mediated by personality, and the findings suggest a new definition of stress as a preoccupation with emotional upset.

Apart from emotional inhibition and rumination, other important factors with implications for stress include coping styles and the type A behavior pattern (TABP). It has been pointed out that there is confusion in the literature over the precise definition of coping, but coping inventories have typically isolated three coping domains involving rational (or problem-focused), emotional, and avoidance strategies. More recent research has uncovered a fourth domain entitled detachment within a four-factor questionnaire, and factor analyses of the four-factor structure has subsequently combined the detached and emotional components into a single bipolar scale that significantly moderates the impact of adaptational stress.

In the same way, a more detailed analysis of TABP has resulted in a reformulation of the construct as a normally distributed dimension of achievement orientation. This work has followed from earlier inconclusive attempts to inadequately distinguish between toxic and nontoxic components of TABP. The more recent research has yielded questionnaires comprising discrete, inversely correlated toxic and nontoxic subscales, in which the former is characterized by hostile competitiveness and the latter by more cooperative achievement styles.

Research with the new scales has shown a consistent pattern of intercorrelations among them and suggested a broader category of toxic behavior that might draw the different strands together. This composite risk index of toxic behavioral tendencies (rumination and emotional inhibition, a tendency towards toxic achievement styles, and a reliance on emotional rather than detached coping) is a potentially powerful tool for predicting deterioration in health status during adaptation, but it does not offer a clear understanding of why some individuals behave in a toxic fashion. Placing the findings on personality and stress in the context of self-esteem offers a way of explaining the findings.

Stress and Self-Esteem

Researchers have speculated that rumination may be the result of factors such as gender or a lack of social support. More fundamentally, however, ruminating about emotional upset may represent an attempt to

preserve self-esteem. TABP has, in fact, been interpreted in this way, by describing type As as having rigid and unrealistic ways of evaluating their own self-worth based on unrealistically high expectations of themselves. A failure to meet these expectations leads to low self-esteem, which these individuals then attempt to compensate for by engaging in the hard-driving, competitive, and aggressive behavior that characterizes TABP. If compensatory behavior is associated with toxic achievement motivation, a positive association might be expected between self-esteem and nontoxic achieving, and this has indeed been found to be the case.

These findings have recently been extended in research examining the costs of attempting to salvage self-esteem when unrealistic expectations are not met. These studies have focused on the goals of efforts to maintain self-esteem and have shown that individuals with purely self-validating goals respond to threats to self-worth in ways that affect both mental and physical health. Clearly, high self-esteem has positive effects on health only when it is pursued in ways that are not contingent on self-validation, a finding that echoes the distinction made earlier between trait and state self-esteem. Noncontingent self-esteem corresponds to a relatively enduring sense of self-worth that is not dependent on others' opinions. Similarly, problem-focused coping strategies are ineffective for highly self-critical perfectionists, but are effective for those with low self-criticism; in the former group, high achievement motivation is undermined by self-criticism, which in turn compromises coping efforts.

Self-esteem has also been shown to act as a buffer against both anxiety and depression. High self-esteem plays a pivotal role in providing protection against anxiety provoked by perceived threats, and in a study that used measures of both optimism and self-esteem to predict postpartum depression, optimism was associated with less depression up to 2 weeks postpartum, but the association with self-esteem was still evident 4 weeks later. Even when the effects of optimism and initial levels of depression were parcelled out, the association between self-esteem and postpartum depression remained.

The stress-buffering effects of self-esteem have been directly tested in experimental studies that used both psychological and physiological measures of stress. These experiments compared groups of subjects who differed in their self-esteem, and the results showed that subjects with high self-esteem suffered less distress, performed better on a cognitive task, and showed less physiological arousal in response to laboratory stressors. The physiological measure in

these studies was heart-rate elevation and recovery, but other research has used direct measures of immune competence to investigate the effects of self-esteem. For example, assays of natural killer (NK) cell activity showed that NK cytotoxicity was significantly suppressed as a consequence of negative self-evaluation.

Conclusion

In conclusion, the evidence implicating self-esteem in human stress responses is unequivocal. Low self-esteem is significantly associated with deleterious psychological, physiological, and immunological consequences, whereas high self-esteem serves a protective or buffering function, and these findings hold true even when the effects of other personality factors are parcelled out. Recent research suggests that self-esteem may act as a superordinate construct that determines the patterning of a wide range of lower-order factors. This model suggests that low self-esteem may govern a range of stress-related personality factors, including emotional inhibition and rumination, the tendency to engage in toxic patterns of achievement behavior such as hostile competitiveness, and the attribution of control externally rather than internally. It is argued that these patterns of behavior are used to compensate for the negative feelings resulting from low self-esteem and that engaging in them serves to perpetuate a maladaptive cycle that becomes self-reinforcing.

Selye's Message

Overview

Hans Selye (Figure 1), born in Vienna in 1907, is internationally acknowledged as the father of stress and, arguably, as the greatest physician of all time. Selye's work on stress has had an enormous impact on biomedical sciences and the practice of medicine. His extraordinary energy resulted in the publication during his lifetime of more than 1450 scientific papers and 22 books, of which 15 are monographs that have been translated into many languages. It is noteworthy that in the past 3 years, more than 20 years after his death in 1982, his publications have received more than 695 citations. His concern about gaining public understanding of this work led him to write several books for the layman, some of which gained great popularity, such as *The stress of life* and *Stress without distress*. Selye was an accomplished linguist able to present his work in many parts of the world, where he was eagerly sought as a speaker. As a lecturer and teacher he inspired countless listeners and students worldwide.

Selye was driven by an insatiable inquisitiveness for the pursuit of truth. Well served by a legendary memory, a great mind, and intuitive skills, he understood the importance of reflection following experimentation and gathered in his laboratories the brain power that was necessary to challenge established truths and generate new paradigms.

Education and Awards

Selye's scientific education began in 1924 at the German University of Prague, where he obtained a

Figure 1 Hans Selye.

PhD in chemistry and a doctorate in medicine. As was customary for medical students at that university, he did part of his training abroad, at the University of Paris and the University of Rome. Selye undertook postdoctoral studies in Prague and then was nominated assistant in experimental pathology in charge of the histology laboratory. In 1931, he was awarded a Rockefeller Research Fellowship to work at Johns Hopkins University in Baltimore. A year later he moved to McGill University in Canada, where he was nominated lecturer and assistant professor in the Department of Biochemistry. In 1937 he joined the Department of Histology, where he was nominated associate professor in 1941. It was in 1945 that Selye moved to the Université de Montreal, where he founded and directed the Institut de Médecine et de Chirurgie expérimentales. He held the position of professor and director until his retirement in 1976. Afterwards, Selye founded and became president of the International Institute of Stress in Montreal as well as professor emeritus until his death in 1982.

Selye was the recipient of many honorary degrees and awards from many countries, including 17 honorary degrees from universities in the United States and abroad, 72 medals and awards (e.g., the American Academy Achievement Golden Award, International Kittay, Killam Award), and 12 diplomas. He was elected Fellow of the Royal Society of Canada in 1941 and in 1968 was appointed Companion of the Order of Canada.

Selye's Message

What was Selye's message? Although the starting points were different, the central theme of all his research from 1936 onward was stress and adaptation to stress. His landmark article published in 1936 in *Nature* titled 'A syndrome produced by diverse noxious agents' described the general adaptation syndrome in response to stress with its three stages (alarm, resistance, exhaustion). Very early during his investigations, Selye recognized the significance of the adrenal gland in adaptation and also demonstrated the importance of the pituitary-adrenocortical axis in the stress reaction. He classified the steroids and named the products of the adrenal cortex corticoids, which he subdivided into glucocorticoids and mineralocorticoids. The key role of glucocorticoids in the treatment of inflammatory and immune disorders was also demonstrated.

It is of interest that in Selye's institute, two postdoctoral fellows, Claude Fortier and Roger Guillemin, initiated work on the mechanisms of hormonal regulation of the pituitary-adrenocortical axis. Guillemin

later identified the presence of the corticotropin-releasing factor (CRF) in the hypothalamus that stimulated the secretion of adrenocorticotropin (ACTH) by the pituitary gland. He was awarded the Nobel Prize in 1977 for this significant contribution to the understanding of the mechanisms of the stress response.

Further studies by Selye lent support to the view that diseases of adaptation were maladies in which derangements of the adaptation syndrome play a key role. This included the demonstration of hormonal conditioning, the influence of hormones upon reactivity, factors influencing the development of cardiac necroses and related lesions, hormonal production of hypertension, nephrosclerosis, and generalized collagen diseases.

Selye's basic studies were conducted using traditional physiological techniques in animals but were followed by many investigations by some of his graduate students and others with sophisticated techniques including neurochemistry and molecular biology. Selye did not pay much attention to these methods, which he called *in vitro* approaches. Instead, he put his trust in nature, "alone capable," as he used to say, of replying to his questions. He wrote a book on this subject, entitled *In vivo: The case for supramolecular biology*, in which he made a point of his generalist approach.

Selye was one of the great men who were not limited by the bounds of a single discipline, in his case physiology, but who covered several fields (endocrinology, immunology, metabolism) and created new disciplines (neuropsychimmunology, neuroendocrinology). His work had an impact on human development, cardiovascular disease, central nervous system depression, and the physiology of mind-body interactions. His article on the stress response published in *Nature* in 1936 has been recognized as a psychiatry classic because it led to the study of the effects of stress and hormones, mainly corticosteroids on brain function. Selye acquired worldwide fame through his description of the physiological and biological effects of stress. Although he worked only with animals and never conducted clinical research on or treated humans, the body of knowledge he generated has had a profound impact on our understanding of the consequences of stress on human development, modulation of immune and endocrine response, and psychobiology. There is no doubt that millions of people have benefited and are benefiting today from the concepts he developed.

Sepsis

A life-threatening reduction in blood oxygenation requiring assisted mechanical ventilation.

Systemic inflammation-associated impairments of vital organs: brain, lung, cardiovascular system, renal, liver, and hematopoietic system.

Systemic inflammation induced by infection.

Introduction

Hundred of thousands of American are affected every year by severe sepsis (700,000) and acute respiratory distress syndrome (ARDS; 190,000) creating a significant short-term and long-term burden on public health and health-care economics. Dysregulated systemic inflammation with persistent elevation of circulating inflammatory cytokines over time is the pathogenetic mechanism for the dysfunction and failure of the vital organs, the leading cause of death in patients with sepsis and ARDS. In sepsis and ARDS, the downregulation of inflammation is *conditio sine qua non* to their resolution. An improved understanding of the cellular mechanisms that initiate, propagate, and restrict inflammation in sepsis and ARDS is essential to make advances on present treatment modalities and to develop more reliable methods of monitoring disease progression and responses to therapy.

It is now appreciated that at cellular level transcription factors nuclear factor (NF)- κ B, which is

activated by inflammatory signals, and the glucocorticoid receptor (GR) α , which is activated by endogenous or exogenous glucocorticoids (GCs), have diametrically opposed functions (stimulatory vs. inhibitory) in regulating inflammation. NF- κ B is recognized as the principal driver of the inflammatory response, being responsible for the transcription of more than 100 genes, including tumor necrosis factor (TNF)- α and interleukin(IL)-1 β (Figure 1). Once activated, NF- κ B and GR α can mutually repress one

another through a protein–protein interaction that prevents their DNA binding and subsequent transcriptional activity. Known interactions between NF- κ B and the activated glucocorticoid receptor (GC-GR α) are depicted in Figure 1. The activation of one transcription factor in excess of the binding (inhibitory) capacity of the other shifts cellular responses toward the increased (dysregulated) or decreased (regulated) transcription of inflammatory mediators over time (Figure 2). The role of GC

Figure 1 Positive regulatory loop interaction between NF- κ B and the activated glucocorticoid receptor (GC-GR α). When cells are stimulated by inflammatory signals, specific kinases phosphorylate the inhibitory protein I- κ B and cause its rapid degradation. The activated form of NF- κ B then moves to the nucleus, initiating the transcription of mRNA of inflammatory cytokines, chemokines, cell adhesion molecules, and inflammation-associated enzymes (cyclooxygenase, phospholipase A2, and inducible nitric oxide). Cortisol or exogenous glucocorticoids freely cross into the cytoplasm and bind to their specific glucocorticoid receptors (GR α) to form GC-GR α . GC-GR α complexes may influence NF- κ B activity in five major ways: (1) physically interacting with the p65 subunit to form an inactive (GC-GR α -NF- κ B) complex, (2) inducing the synthesis of the inhibitory protein I- κ B α via interaction with glucocorticoid-responsive element DNA in the promoter of the I- κ B gene, (3) blocking the degradation of I- κ B α via enhanced synthesis of IL-10, (4) impairing the TNF- α -induced degradation of I- κ B α , and (5) competing for limited amounts of GR co-activators such as cAMP response element binding protein (CREB)-binding protein (CBP) and steroid receptor coactivator (SRC-1). I- κ B α , in addition to holding NF- κ B in an inactive cytoplasmic state, also translocates into the nucleus, where it binds activated NF- κ B complexes to induce their export to the cytoplasm. GC-GR α may also decrease the stability of mRNA of several inflammatory cytokines and other molecules. The products of the genes that are stimulated by NF- κ B activate this transcription factor. Thus, TNF- α and IL-1 β both activate and are activated by NF- κ B by forming a positive regulatory loop that amplifies and perpetuates inflammation. Reproduced with permission from Meduri, G. U., Muthiah, M. P., Carratu, P., et al. (2005), Nuclear factor-kappaB- and glucocorticoid receptor alpha-mediated mechanisms in the regulation of systemic and pulmonary inflammation during sepsis and acute respiratory distress syndrome: evidence for inflammation-induced target tissue resistance to glucocorticoids, *Neuroimmunomodulation* 12(6), 321–338.

Figure 2 Regulated response interaction between NF-κB and the activated glucocorticoid receptor (GC-GRα). GC-GRα activation sufficient to maintain NF-κB levels in homeostasis and achieve a reduction in the transcription of inflammatory mediators over time is shown. In improvers, both GC-GRα binding to NF-κB and nuclear GC-GRα binding increased significantly over time, indicating an excess activation of GC-GRα compared to NF-κB (GC-GRα-driven response). Reproduced with permission from Meduri, G. U., Muthiah, M. P., Carratu, P., et al. (2005), Nuclear factor-kappaB- and glucocorticoid receptor alpha-mediated mechanisms in the regulation of systemic and pulmonary inflammation during sepsis and acute respiratory distress syndrome: evidence for inflammation-induced target tissue resistance to glucocorticoids, *Neuroimmunomodulation* 12(6), 321–338.

supplementation in patients with life-threatening systemic inflammation is undergoing a cyclical reassessment, stirred by a new understanding of the role of GCs in regulating inflammation and the positive results of recent randomized controlled studies.

Acute Respiratory Distress Syndrome

ARDS is a life-threatening form of hypoxemic respiratory failure (mortality of 30–60%) that develops within 12–48 h of a patient's acquiring an acute illness complicated by severe systemic inflammation. The most common condition precipitating ARDS is severe sepsis, and the mortality rate for sepsis-induced ARDS has not significantly decreased in the last 20 years. In ARDS, the evolution (regulated vs. dysregulated) of systemic inflammation in the first week of mechanical ventilation determines the physiological progression of the disease and the final outcome. Patients failing to improve in the first week of mechanical ventilation (nonimprovers) have, compared to improvers, a persistent elevation in circulating and bronchoalveolar lavage (BAL) levels of inflammatory cytokines and chemokines, markers of

alveolocapillary membrane (ACM) permeability and fibrogenesis. In sepsis and ARDS, the downregulation of inflammation is essential for the restoration of homeostasis and survival.

Systemic Inflammation-Associated Glucocorticoid Resistance

GCs as end effectors of the hypothalamic-pituitary-adrenal (HPA) axis are the most important physiological inhibitors of inflammation, affecting hundreds of genes involved in stress-related homeostasis. However, endogenous GCs are not always effective in suppressing life-threatening systemic inflammation, and the degree of cortisolemia frequently correlates with the severity of illness and the mortality rate. Unquestionably, the elevation of GC secretion in non-survivors of sepsis and ARDS is inadequate to meet the needs of the concurrent inflammatory response and its adverse systemic effects. Its failure to suppress inflammation could be due to tissue resistance to GCs, the inadequacy of the level and duration of endogenous GC elevation to suppress a systemic inflammatory response gone awry, or both.

The concept of acquired GC resistance was first introduced by Kass and Finland in 1957. These investigators suggested that increased blood cortisol levels in nonsurvivors of sepsis might reflect a blocking of steroidal activity or transport as a consequence of the infection. In this situation, a small increase in blood levels with a low (equal to or less than physiological) dose of exogenous GCs was believed to be sufficient to facilitate the passage of steroids into host cells. GC resistance was originally described as a primary inherited familial syndrome and was recently recognized as an acquired condition. Among others, acquired immune tissue-specific GR resistance has been described in patients with asthma, acquired immunodeficiency syndrome (AIDS), severe sepsis, and sepsis-induced ARDS.

In vitro studies showed that cytokines may induce resistance to GCs by reducing GR binding affinity to cortisol and/or GC response elements (GREs). Such abnormalities of GR function were demonstrated in T cells incubated with a combination of interleukin (IL)-2 and IL-4, IL-1, IL-6, and interferon (IFN)- γ , or IL-13. GC resistance was induced in a cytokine concentration-dependent fashion and was reversed by the removal of cytokines. GR-mediated resistance in the presence of systemic inflammation was also studied in experimental models of sepsis and sepsis-induced ARDS. In a sheep model of sepsis-induced ARDS, the maximal binding capacity of GR decreased continuously after endotoxin infusion, whereas there was a marked elevation of cortisol levels. The reduced GR binding correlated negatively ($r = -0.87$, $p < 0.01$) with phospholipase A₂ (PLA₂) activity, a gene that is stimulated by NF- κ B. In a rat model of septic shock, GR blockade by mifepristone (RU 486) exacerbated the physiological and pathological changes induced by endotoxemia. PLA₂ activity in rats with 80% GR blockade was more marked than in those with 50% GR blockade. The monocytes of patients with sepsis developed near-total GC resistance *in vitro* when cytokines, especially IL-2, were added.

Nuclear Factor κ B and Glucocorticoid Receptor α Interaction

New evidence indicates that a primary pathogenetic mechanism explaining GC resistance or insensitivity in patients with life-threatening systemic inflammation is the imbalance between excessive NF- κ B activation by inflammatory signals and deficient GR α activation by endogenous or exogenous glucocorticoids. Using an *ex vivo* model of systemic inflammation, our group investigated intracellular upstream and downstream events associated with DNA binding

of NF- κ B and GR α in naïve peripheral blood leukocytes (PBLs) stimulated with longitudinal plasma specimens obtained from 28 patients with sepsis-induced ARDS and correlated the physiological progression with laboratory findings. Exposure of naïve cells to longitudinal plasma samples led to divergent directions in NF- κ B and GR α activation that reflected the severity of systemic inflammation (defined by plasma TNF- α and IL-1 β levels). The activation of one transcription factor in excess of the other shifted cellular responses toward decreased (GR α -driven) or increased (NF- κ B-driven) transcription of inflammatory mediators over time (Figures 2–3).

Plasma samples from patients with declining inflammatory cytokine levels over time elicited a progressive increase in all measured aspects of GC-GR α -mediated activity ($p = 0.0001$) and a corresponding reduction in NF- κ B nuclear binding ($p = 0.0001$) and transcription of TNF- α and IL-1 β (regulated, GR α -driven response; Figure 2). In contrast, plasma samples from patients with sustained elevations in inflammatory cytokine levels over time elicited only modest longitudinal increases in GC-GR α -mediated activity ($p = 0.04$) and a progressive increase in NF- κ B nuclear binding over time ($p = 0.0001$) that was most striking in nonsurvivors (dysregulated, NF- κ B-driven response; Figure 3). These findings demonstrate that insufficient GC-GR α -mediated activity is an important mechanism for early loss of autoregulation (i.e., downregulation of NF- κ B activation) in nonimprovers. Deficient GR α activity in naïve cells exposed to plasma from patients with dysregulated inflammation was observed despite elevated circulating cortisol and adrenocorticotrophic hormone (ACTH) levels, implicating inflammatory cytokine-driven excess NF- κ B activation as an important mechanism for target-organ insensitivity and/or resistance to cortisol.

Our findings are in agreement with two longitudinal studies that investigated NF- κ B binding activity directly in the peripheral blood mononuclear cells of patients with sepsis or trauma. In both studies, nonsurvivors (compared to survivors) had a progressive increase in NF- κ B activity over time. In one longitudinal study, nonsurvivors of septic shock had by days 2–6 a 200% increase in NF- κ B activity compared to day 1. Similarly, using our *ex vivo* model we found that NF- κ B binding activity on day 3 of ARDS clearly separated patients by outcome. In an immunohistochemistry analysis of lung tissue, areas with severe (vs. mild) ARDS had a higher nuclear uptake of NF- κ B (13 ± 1.3 vs. 7 ± 2.9 ; $p = 0.01$) and a lower ratio of GR α : NF- κ B nuclear uptake (0.5 ± 0.2 vs. 1.5 ± 0.2 ; $p = 0.007$). Thus, an uninhibited increase in NF- κ B activation in circulating cells over time

Figure 3 Dysregulated response interaction between NF-κB and the activated glucocorticoid receptor (GC-GRα). An excess of NF-κB activation is shown, leading to the protracted transcription of inflammatory mediators over time. In nonimprovers, GC-GRα binding to NF-κB was modestly increased, whereas nuclear NF-κB binding increased substantially over time and nuclear GC-GRα and cytoplasmic IκBα levels declined (NF-κB-driven response). Reproduced with permission from Meduri, G. U., Muthiah, M. P., Carratu, P., et al. (2005), Nuclear factor-kappaB- and glucocorticoid receptor alpha-mediated mechanisms in the regulation of systemic and pulmonary inflammation during sepsis and acute respiratory distress syndrome: evidence for inflammation-induced target tissue resistance to glucocorticoids, *Neuroimmunomodulation* 12(6), 321–338.

appears to be a significant premortem pathogenetic component of lethal sepsis and ARDS.

Systemic Inflammation-Induced Glucocorticoid Resistance Can Be Improved with Prolonged Glucocorticoid Supplementation

Our findings place GC-GRα-mediated downregulation of NF-κB activity as a critical factor for the reestablishment of homeostasis during the acute, life-threatening systemic inflammation that accompanies sepsis and ARDS. A subgroup of 11 patients with dysregulated inflammation and deficient GC-GRα activity were randomized to prolonged GC supplementation initiated on ARDS day 9 ± 3 . Quantitatively adequate and prolonged hormonal supplementation restored GR anti-inflammatory function, decreasing the production of inflammatory cytokines, inflammatory cytokine-driven HPA axis activity, and inflammatory cytokine-driven organ dysfunction. Normal PBL exposed to plasma samples collected during GC versus placebo treatment exhibited rapid, progressive, and significant increases in

GRα-mediated activities (GRα binding to NF-κB, GRα binding to GRE DNA, stimulation of inhibitory protein IκBα, and stimulation of IL-10 transcription) and significant reductions in NF-κB κB binding and transcription of TNF-α and IL-1β. During GC treatment, the relationship between NF-κB and GC-GRα signaling pathways changed from an initial NF-κB-driven and GC-GRα-resistant state to a GC-GRα-driven and GC-GRα-sensitive one. In aggregate, the findings indicate that systemic inflammation-induced GC resistance is an acquired generalized process mediated by excess NF-κB activation and potentially reversible by increasing GC-GRα activation with quantitatively adequate and prolonged GC supplementation.

Findings of Randomized Trials

At present, the administration of low-dose GCs is the only treatment shown in randomized trials to have a significant positive biological and physiological effect across the longitudinal spectrum of the severity of sepsis-associated systemic inflammation: severe sepsis, septic shock, early ARDS, and unresolving ARDS.

Table 1 Prolonged glucocorticoid treatment in sepsis and ARDS: effect on mortality^a

Severity of sepsis	Number of RCTs	Number of patients (death of total)			Source ^b
		Treated	Control	p value

10. Yildiz, O., Doganay, M., Aygen, B., et al. (2002), Physiological-dose steroid therapy in sepsis, *Critical Care* **6**(3), 251–259.

All randomized studies showed significant physiological improvement and a reduction in the duration of stays in the intensive care unit. The overall effects on mortality are shown in [Table 1](#).

In prolonged low-dose GC treatment, maximal benefits are obtained by (1) avoiding the premature removal of an effective drug, leading to rebound inflammation and physiological deterioration, and (2) preventing potential complications associated with GC treatment (infection surveillance and avoidance of paralysis). Uncontrolled studies have also shown a likely benefit in patients with viral pneumonia-induced ARDS, including SARS. The mortality rate in 849 cases of SARS treated with antiviral therapy and GC supplementation was only 7.7%. In hantavirus pulmonary syndrome, the mortality rate decreased from 47% in patients treated with antiviral therapy to 13% when GC supplementation was also included. The findings for severe viral pneumonia and the results of recent randomized controlled trials (RCTs) for ARDS indicate that prolonged methylprednisolone use might be useful in the prevention of morbidity and mortality associated with avian influenza.

Conclusion

Dysregulated systemic inflammation has enormous health-care consequences. A new understanding of the cellular mechanisms responsible for inflammation-associated GC resistance provides a new rationale for investigating prolonged low-dose GC supplementation. The consistent positive results of small- to moderate-size randomized studies are very encouraging. Federal financial support is urgently needed to conduct additional RCTs investigating this inexpensive off-patent treatment in patients with life-threatening systemic inflammation.

Serotonin and Adrenocortical Function

Serotonin and Renal Function

Conclusion

Glossary

5-Hydroxytryptamine (5-HT) receptors

Plasma membrane proteins that mediate the biological effects of serotonin through the activation of an intracellular second-messenger system. There are at least seven different classes of 5-HT receptors, which are defined according to their pharmacological properties using selective agonists and antagonists and/or their molecular structure as determined by molecular cloning techniques; some of these classes of 5-HT receptors have been divided further into subclasses. Not all of the 5-HT receptors identified have yet been assigned a clear biological function.

Aromatic-L-amino acid decarboxylase (L-AAAD)

A chemical (EC 4.1.1.28) that catalyzes the decarboxylation of L-5-hydroxytryptophan and L-dopa (L-3,4-dihydroxyphenylalanine) to serotonin and dopamine (3,4-dihydroxyphenylethylamine), respectively. It requires pyridoxal phosphate as a coenzyme and occurs most abundantly in the kidney, liver, gastrointestinal tract, adrenal gland, and brain; previously known as hydroxytryptophan decarboxylase or dopa decarboxylase.

Serotonin (5-hydroxytryptamine, 5-HT)

A biogenic amine (first isolated from serum by Irvine Page in 1948) shown to affect vascular tone. Its other name (adopted by Erspamer in the 1940s) was enteramine because it was found to be associated with enterochromaffin cells of the gastric mucosa. By the 1950s, the chemical structure was established and serotonin/enteramine was renamed 5-hydroxytryptamine.

Zona fasciculata

A broad layer of cells in contact with the zona glomerulosa and forming the main mass of the adrenal cortex. These cells

secrete the steroid hormones cortisol (in humans) and corticosterone (in rodents). These steroids act on glucocorticoid receptors, which are distributed very widely in mammalian tissues, and produce many different biological actions, including the breakdown of carbohydrates, proteins, and fats.

Zona glomerulosa

A narrow layer of cells in the outer region of the adrenal gland, situated directly beneath the adrenal capsule, whose specific function is to secrete the steroid hormone aldosterone, which acts on mineralocorticoid receptors in the distal convoluted tubule of the kidney to cause sodium retention and potassium loss.

Serotonin and Adrenocortical Function

In Vitro Effects of Serotonin in the Adrenal Cortex

The stimulatory effect of 5-HT on adrenocortical steroidogenesis in several species, including the rabbit, guinea pig, rat, and human, was discovered by Rosenkrantz in 1959. Based on the sodium-retaining effects and chromatographic properties, the steroid stimulated by 5-HT was identified as aldosterone, which is synthesized in the zona glomerulosa cells of the adrenal cortex. Concurrent experiments demonstrated that rat serum (but not rat plasma) stimulated steroid production in the rat zona glomerulosa, indicating that a component of the blood-clotting system (later identified as 5-HT) was involved. These landmark experiments led to subsequent studies by numerous workers to determine the role of 5-HT in adrenocortical function. Most of these studies were carried out in rat models for the reason that the zona glomerulosa in this species can be cleanly dissected from the zona fasciculata and zona reticularis and, following enzymatic disaggregation of the tissue, the zona glomerulosa cells can be obtained with less than 5% contamination by other cell types. When rats are placed on a low sodium chloride diet, the sensitivity of the aldosterone response to 5-HT is increased in the zona glomerulosa. Conversely, when either a high sodium chloride diet or a low potassium chloride diet is given, the zona glomerulosa cells become less sensitive to 5-HT. This clearly indicates a dependency of the aldosterone response to 5-HT on the sodium/potassium status, which is also observed for other zona glomerulosa-specific stimuli, such as angiotensin II and plasma potassium. In contrast, no

direct steroidogenic response to 5-HT is found in cells of the zona fasciculata or zona reticularis. The stimulation of aldosterone by 5-HT is associated with an increase in cAMP in rat zona glomerulosa cells, and these responses are inhibited by 5-HT antagonists such as methysergide, cyproheptadine, and ketanserin, indicating the presence of 5-HT cell surface receptors in the zona glomerulosa. Although this receptor was identified tentatively as a 5-HT₂ receptor (now renamed the 5-HT_{2A} receptor) based on the effects of ketanserin, subsequent cloning of this receptor did not support this notion. No mRNA for this receptor (which is coupled to phospholipase C) has been found in zona glomerulosa cells, and 5-HT does not stimulate phospholipase C in these cells. The 5-HT receptor in rat zona glomerulosa cells still awaits clear identification. In human zona glomerulosa cells, the 5-HT receptor has been partially characterized, pharmacologically, as a 5-HT₄ receptor (which couples to adenylate cyclase), and the 5-HT₄-selective agonist zacopride is a potent stimulus to aldosterone in human zona glomerulosa tissue. In both rat and human zona glomerulosa cells, 5-HT-stimulated aldosterone secretion is also coupled to Ca²⁺ influx and is inhibited by verapamil, suggesting the involvement of voltage-dependent Ca²⁺ channels.

Ex Vivo Effects of Serotonin in the Adrenal Cortex

In the isolated perfused rat adrenal gland, 5-HT increases the perfusion flow rate, which correlates with the increased secretion of both aldosterone and corticosterone. No 5-HT receptors have been characterized in the adrenal vasculature to date, but because the blood flow rate is an important determinant for steroid secretion *in vivo*, these potential vascular effects of 5-HT in the adrenal cortex could be important physiologically.

In Vivo Effects of Serotonin on Adrenocortical Steroidogenesis

Infusions of high doses of 5-HT in humans cause an increase in aldosterone but not cortisol secretion. Because plasma levels of 5-HT are normally extremely low, due to the active 5-HT reuptake mechanism in the platelets, the potential physiological relevance of this observation is unclear. The administration of the 5-HT precursors L-tryptophan and 5-hydroxytryptophan (5-HTP) in humans produces an increase in both aldosterone and cortisol secretion, and it is thought that these effects are mediated by the activation of the hypothalamic–pituitary–adrenal (HPA) axis because it has been demonstrated clearly in rat tissues *in vitro* that 5-HT can stimulate both corticotropin releasing hormone (CRH) release and adrenocorticotrophic

hormone (ACTH) release. Intraperitoneal injections of 5-HTP in rats lead to an increase in both aldosterone and corticosterone secretion and plasma renin activity *in vivo*. The corticosterone response to 5-HT can be completely inhibited by the co-administration of dexamethasone, whereas the aldosterone response to 5-HTP is only partially inhibited. The co-administration of the angiotensin-converting enzyme inhibitor captopril partially inhibits the aldosterone response to 5-HTP treatment and does not affect the corticosterone response. These studies therefore indicate that corticosterone (a zona fasciculata steroid) can be regulated by 5-HT *in vivo* by the stimulation of the HPA axis, whereas the aldosterone response is more complex, involving the activation of the HPA axis, the renin–angiotensin system, and, in addition, direct effects in the zona glomerulosa. The effects of 5-HT on renin release are thought to be centrally mediated because 5-HT does not stimulate renin release in the kidney. The notion that the direct effects of 5-HT on zona glomerulosa cells could be an important physiological control mechanism for aldosterone secretion is supported by studies that demonstrate that infusions of the 5-HT₄-selective agonist zacopride in humans increase plasma aldosterone but not plasma cortisol.

Sources of Serotonin in the Adrenal Gland

The physiological source of 5-HT that regulates aldosterone secretion in the zona glomerulosa has not been clearly identified to date. Although 5-HT has been located in the adrenal medulla of some species, including the rat and pig by immunohistochemical techniques, the centripetal blood flow in the adrenal gland from the outer cortex to the inner medulla argues against any significant influence of medullary secretory products on adrenocortical function. In the rat, mast cells (which store 5-HT) have been found in the subcapsular portions of the adrenal artery, and drugs that cause mast-cell degranulation can stimulate aldosterone secretion in the perfused rat adrenal gland. Physiological mechanisms leading to the specific release of 5-HT from these mast cells within the adrenal cortex, however, have not been identified. Other studies have focused on platelets as a possible physiological source of adrenocortical 5-HT. The use of ¹⁴C-radiolabeled 5-HT to track the platelet deposition of 5-HT *in vivo* in rats has demonstrated that 5-HT can potentially be released in some endocrine tissues, including the thyroid gland and the adrenal gland, but the release mechanisms are unclear. Perhaps the most likely source of adrenocortical 5-HT is the enzyme L-AAAD, which has been found, by immunohistochemistry, to be specifically associated with the zona glomerulosa in the rat adrenal cortex.

This enzyme converts 5-HTP (which circulates in plasma and is not stored in platelets) to 5-HT and can be inhibited by carbidopa. The incubation of rat adrenal zona glomerulosa tissue *in vitro* with 5-HTP, at physiological concentrations, leads to an increase in aldosterone and 5-HT, and both are completely inhibited in the presence of carbidopa. Furthermore, this enzyme in the zona glomerulosa appears to be regulated by changes in the dietary sodium chloride intake in parallel with observed changes in aldosterone secretion. Thus, the enzyme activity is increased by a low sodium chloride intake and is decreased by a high sodium chloride intake.

Serotonin and Renal Function

Effects of Serotonin on Renal Vasculature

The effects of 5-HT on the renal circulation are variable, depending on the species studied. Most investigations have been carried out in rats or dogs, with few comprehensive studies in humans. The administration of 5-HT to rats *in vivo* (by infusion or intraperitoneal injection) increases renal vascular resistance and reduces the renal blood flow rate. These effects are also observed in the *ex vivo*-isolated perfused rat kidney, are independent of intact renal nerves, and are inhibited by ketanserin, a 5-HT_{2A} antagonist. In the dog, similar effects are observed, although they are clearly more dependent on renal innervation, in that the stimulation of the sympathetic nerves results in a vasodilator response to 5-HT rather than a vasoconstriction. It has been suggested that 5-HT_{1D} receptors may be more important in mediating 5-HT-induced renal vasoconstriction than 5-HT_{2A} receptors in the dog because the 5-HT agonist sumatriptan can reduce renal blood in the presence of a ketanserin blockade. The 5-HT receptor that mediates renal vasodilatation in the dog has not been characterized, although it is thought to be associated with the vascular endothelium and to be coupled to nitric oxide production. Most studies in humans have indicated either no change or only a modest reduction in renal plasma flow and glomerular filtration rate (GFR) in response to intravenous 5-HT. The physiological role of 5-HT in modulating renal hemodynamics in humans is therefore still unclear.

Effects of Serotonin on Renal Tubule Function

In rats, intravenous or intraperitoneal administration of 5-HT causes a decrease in the urine flow rate and a reduction in sodium excretion. Both the antidiuretic and the antinatriuretic effects of 5-HT are thought to involve a direct effect on tubular function, although the antinatriuretic could be partially mediated by

5-HT-stimulated aldosterone secretion. Similarly, in dogs, 5-HT can produce both antidiuresis and antinatriuresis, and these effects are inhibited by the non-selective 5-HT₁ antagonist methysergide. In humans, most studies show that 5-HT infusions lead predominantly to an antinatriuretic effect, with no significant or only modest antidiuresis. Similar responses are observed in response to 5-HTP.

Renal Sources of Serotonin

Although blood platelets store 5-HT, which can be released in certain disease states characterized by intravascular coagulation, it is unlikely that platelet 5-HT contributes to the effects of 5-HT on renal function in normal physiological conditions. Renal tissue, however, can synthesize 5-HT from the precursor 5-HTP via the action of L-AAAD, which is found throughout the renal cortex and also in the renal medulla. Immunostaining for L-AAAD is particularly intense in the renal tubules of the rat kidney, the site of action for 5-HT in relation to its antinatriuretic effect.

Actions of Serotonin Renal Prodrugs

Renal prodrugs are essentially precursors of biologically active endogenous compounds that are preferentially metabolized to the active compound in the kidney. An intravenous infusion of either 5-HTP or the renal prodrug γ -L-glutamyl-5-hydroxy-L-tryptophan (γ -glutamyl-5-HTP) in humans reduces sodium excretion and increases urinary 5-HT excretion due to their metabolism to 5-HT within the kidney. In the presence of carbidopa, which inhibits the activity of L-AAAD, the sodium retention caused by these drugs and their metabolism to 5-HT are completely abolished.

Conclusion

5-HT is a stimulus for both mineralocorticoid (aldosterone) and glucocorticoid (cortisol and corticosterone) secretion. Within the adrenal cortex, 5-HT is a specific stimulus for aldosterone secretion in the zona glomerulosa. In the kidney, the renal hemodynamic effects of 5-HT still require clarification, especially in humans, whereas the antinatriuretic effects of 5-HT are reproducible in several species, including humans. The enzyme L-AAAD is likely to play a key role in the local production of 5-HT in the adrenal cortex and in the kidney. It seems logical that the actions of 5-HT within the adrenal cortex and the kidney are coordinated in order to maintain sodium homeostasis, and it will therefore be important to understand the mechanisms that regulate the activity of L-AAAD in these tissues.

<i>Serotonin (5-hydroxytryptamine, 5-HT)</i>	A widely distributed monoamine that has been involved in almost every function of the brain.

Stress and Psychopathology: Possible Role of Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is a widely distributed monoamine that has been involved in almost every function of the brain. It is known that serotonin acts through a complex receptor system (5-HT₁–5-HT₇), with the number of receptors showing regional variation in terms of their distribution. The brain serotonergic system originates predominantly from cell groups located in either the dorsal or the median raphe nuclei, but some cell bodies are located in the ventrolateral region of the midbrain. Serotonergic neurons have a major influence on the regulation of neuroendocrine function, cardiovascular and respiratory activity, sleep, pain sensitivity, and mood. Serotonin furthermore acts as a growth factor during embryogenesis, and serotonin receptor activity forms a crucial loop in the pathway leading to changes in brain structure. There is extensive evidence for a role of serotonin in human illnesses associated with disrupted brain functioning.

Similarly, stress is involved in many aspects of human disease. At least part of this involvement could be caused by or associated with effects of stress on the serotonergic system and its widespread functions. For example, some of the physiological changes

associated with the stress response include enhanced cardiovascular output and respiration, modulation of the immune response, increased cerebral perfusion, and mobilization of energy to maintain brain function. Also more subtle changes in behavioral functioning caused by stress, e.g., arousal, anxiety, and cognition, may involve brain serotonin. Psychological stress, furthermore, can have an important role in the onset and course of mental illness, including depression, anxiety, and schizophrenia.

The influence of stressful life events in humans has received widespread attention. Exposure to early life stress is associated with neurobiological changes in children and adults, which may underlie the increased risk of psychopathology. There is substantial evidence that early life events influence serotonergic function in the brain as well as brain development and subsequent adult behavior. For example, the effects of early traumatic events on the developing brain and the biological abnormalities found in subjects with schizophrenia include hyperactivity of the hypothalamic-pituitary-adrenocortical (HPA) axis and serotonin abnormalities, and structural changes to the brain such as damage to the hippocampus, a brain region enriched in serotonin receptors. Stress accelerates both the release and turnover of brain serotonin. This can lead to restoration of homeostasis, whereas chronic stress can induce a long-lasting imbalance in central nervous neurotransmitter systems, including serotonin. Abuse and neglect during early childhood is linked to low levels of serotonin and risk for hostility, aggression, substance abuse, and suicide.

Several other lines of evidence have linked brain serotonin activity with human psychopathology. A polymorphism in the promoter region of the serotonin transporter gene has been suggested to contribute to anxiety in humans, and the presence of an allele encoding a short sequence in this promoter region increases the risk for the development of a depressive disorder. Studies in a population of rhesus monkeys have shown that the short sequence allele corresponds to low concentrations of the serotonin metabolite 5-hydroxyindolacetic acid in the cerebrospinal fluid. Mutations in the gene for the enzyme tryptophan hydroxylase may also predispose to mood disturbances. Alterations in the several synaptic proteins, transcription factors, and proteins involved in neuronal growth/differentiation that are modified in their expression in experimental models of chronic stress can be reversed by treatment with antidepressants, thus suggesting an important role for the serotonin system.

Stress, Serotonergic Drugs, and Human Psychopathology

Evidence for the importance of the serotonin system in depression and anxiety disorders has increased substantially over the recent years, and stress plays a major role in the development of these disorders. The first effective antidepressants (tricyclic antidepressants and monoamine oxidase inhibitors) such as imipramine and iproniazid relied at least in part on their ability to increase serotonin and norepinephrine levels in the synapse. Research on the biological effects of these drugs led to the hypothesis of a deficiency in both these cerebral monoamines in depression. Antidepressants act not only on depressive symptoms but also on anxiety. Most of the evidence suggests that depletion of serotonin in the brain increases anxiety in humans. Thus, drugs that increase the levels of serotonin have anxiolytic effects. A new generation of antidepressants that selectively inhibit the neuronal reuptake of serotonin (selective serotonin reuptake inhibitors [SSRIs]) specifically focused on serotonin neurotransmission with little or no activity on noradrenergic mechanisms. Several drugs, including fluoxetine, citalopram, and paroxetine, had the same clinical efficacy, yet appeared to be better tolerated and lack most of the adverse side effects of tricyclic antidepressants and monoamine oxidase (MAO) inhibitors. Originally introduced for the treatment of depression, the SSRIs have been used as the first-line treatment for a broad range of psychiatric disorders, including anxiety, obsessive-compulsive disorder, social phobia, and posttraumatic stress disorder. The target of SSRIs is the presynaptic serotonin transporter protein, which is responsible for clearance of synaptic and plasma serotonin.

Effect of Stress on Serotonin Parameters

Stress increases concentrations of serotonin and its metabolites in several brain regions indicating increased turnover rates of the neurotransmitter. Moreover, stress increases the activity of tryptophan hydroxylase, the biosynthetic enzyme confined to serotonin-producing cells. Therefore, studies of the effect of stress on serotonergic function in laboratory animals may lead to a better understanding of the biological bases of psychopathology.

Repeated exposure of rats to forced swimming increased serotonin concentrations in the striatum but reduced serotonin levels in the lateral septum. Chronic restraint stress in rats revealed increased serotonin turnover in the hippocampus, whereas chronic social defeat in mice upregulated expression of the MAO-A gene in the raphe nuclei. MAO-A is an isoenzyme that

preferentially oxidizes serotonin. An upregulated expression of the MAO-A gene accelerates serotonin degradation and is associated with enhanced expression of the serotonin transporter.

Furthermore, early life stress such as maternal deprivation can affect several aspects of serotonin transmission later in life. For example, maternal deprivation at postnatal day 3 has long-term effects on the serotonergic responsiveness of CA1 pyramidal neurons in the hippocampus of the rat. Adult CA1 hippocampal cells from maternally deprived rats compared to nondeprived rats show a significantly attenuated response to serotonin. This attenuation is also seen in adult rats subjected to high doses of exogenously administered corticosterone or to chronic stress.

Corticosterone regulates hippocampal physiology, particularly in the CA1 region, and the 5-HT_{1A} receptor effector pathway. However, prolonged elevation of the corticosteroid concentration does not alter 5-HT_{1A} receptor mRNA levels in pyramidal neurons. In addition, in rats that were subjected to unpredictable stressors for 3 weeks and that displayed increased adrenal weight and attenuated body weight compared with controls, the 5-HT_{1A} receptor mRNA expression was not changed after chronic stress exposure. Therefore, stress may alter serotonergic function possibly by posttranslational modification of the specific serotonin receptor subtype or changes in the serotonin receptor signal transduction pathway.

Effect of Serotonergic Drugs on Stress Responses

Serotonin and HPA Axis Activity

The primary neuroendocrine response to acute stress includes increased secretion of cortisol in humans or corticosterone in rodents. Glucocorticoid hormones are the final effectors of the HPA axis that participate in the control of homeostasis and the response of the body to stressors. Corticosterone acts on both the high-affinity mineralocorticoid receptors and the lower affinity glucocorticoid receptors. Mineralocorticoid receptors are found in some limbic brain structures that are also rich in serotonin innervation, such as the hippocampus, whereas glucocorticoid receptors are found in several brain regions, including frontal cortex and hypothalamic paraventricular nucleus. Glucocorticoids play a key regulatory role in the termination of the stress response by exerting negative feedback at the levels of hypothalamus and pituitary, and there is increasing evidence to link serotonin with HPA regulation. Serotonin-containing neurons directly innervate corticotropin-releasing hormone (CRH)-containing cells located in the paraventricular

nucleus of the hypothalamus. Serotonergic innervation of the paraventricular nucleus modulates the release of CRH, leading to the release of adrenocorticotrophic hormone (ACTH), which triggers glucocorticoid secretion from the adrenal cortex. Furthermore, administration of the serotonin precursors L-tryptophan and 5-hydroxytryptophan stimulates ACTH and cortisol release, as does the serotonin releasing agent fenfluramine. 5-HT_{1A} and 5-HT_{2A} receptors are the main serotonin receptors mediating serotonergic stimulation of the HPA axis. Activation of 5-HT_{1A} and 5-HT_{2A} receptors increases plasma corticosterone levels. Conversely, the stimulatory effect of serotonin on CRH secretion was antagonized by the 5-HT₁ and 5-HT₂ receptor antagonist metergoline and by the selective 5-HT₂ receptor antagonists ketanserin and ritanserin. Furthermore, administration to rats of the 5-HT_{1A} agonist, 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), resulted in activation of the HPA axis as evidenced by increased plasma ACTH and corticosterone concentrations. Chronic administration of 8-OH-DPAT resulted in increased CRH concentrations in the piriform cortex, entorhinal cortex, amygdala, and hippocampus. However, administration of 8-OH-DPAT had no effect on the 5-HIAA/5-HT ratio. In contrast, 8-OH-DPAT treatment was able to decrease plasma corticosterone responses following acoustic stress, conditioned fear, and cocaine administration. This indicates that the predominant effect of 8-OH-DPAT on adrenocortical responses is mediated at postsynaptic sites not involved in the regulation of cerebral biogenic amine metabolism.

Acute administration of SSRIs stimulates the HPA axis, whereas continuous treatment desensitizes it. The immediate effect of SSRIs on the HPA axis function occurs in the hypothalamic paraventricular nucleus via postsynaptic serotonin receptors on CRH neurons. It is likely that serotonin 5-HT_{1A} and 5-HT_{2A} postsynaptic receptors are indirectly stimulated by SSRI administration.

Physiological Responses: Blood Pressure/Body Temperature

A typical neuroendocrine response also involves the increased secretion of catecholamines (epinephrine and norepinephrine) from the sympathetic nervous system and adrenal medulla. Central catecholamine neurons play a critical role in cardiovascular responses to stress-related stimuli. Hypertension and increased heart rate are key components of the cardiovascular response to stress, leading to the essential increase in tissue perfusion that has to occur in stressful situations. Among the complex interactive systems that contribute to the central regulation of cardiovascular

function, many areas are under the direct influence of serotonergic pathways. Both blood pressure and heart rate may be increased or decreased by the activation of distinct brain serotonin receptors. For example, pharmacological activation of central 5-HT₃ receptors evokes a significant hypotensive effect in rats. By contrast, activation of 5-HT₂ receptors in the lateral hypothalamus and in the paraventricular nucleus increases blood pressure and heart rate. Intraventricular injection of the 5-HT_{2C} agonist (1-(3-chlorophenyl)piperazine) (mCPP) elicited a significant increase in blood pressure in nonstressed animals. However, injection of mCPP did not change the hypertensive or heart rate responses induced by restraint stress. Furthermore, cardiovascular effects caused by the central administration of mCPP were blocked by pretreatment with the 5-HT_{2C} antagonist SDZ SER 082. Conversely, administration of SDZ SER 082 blunted stress-induced hypertension without modifying stress-induced increase in heart rate. Several serotonergic drugs with full or partial 5-HT_{1A} receptor agonist activity, such as 8-OH-DPAT, buspirone, and MDL 73,005EF, were shown to reduce both blood pressure and heart rate responses to open-field novelty stress (Figure 1). This effect was seen without changes in the exploratory locomotor activity response in this test.

Administration of serotonergic drugs may affect other physiological responses associated with stress, such as body temperature changes. Acute administration of 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) is associated with rapid hyperthermia that can last several hours and is linked to monoamine release from nerve endings in the brain. In addition to hyperthermia, other, often fatal, physiological problems occur, including tachycardia, renal failure, edema, and thrombocytopenia. MDMA acts by releasing monoamines, including serotonin, but the receptor mechanisms underlying MDMA-induced hyperthermia and cutaneous vasoconstriction remain unclear. MDMA-induced hyperthermia is associated with reduced cutaneous blood flow, which may contribute to the hyperthermia by diminishing normal heat transfer from the body to the environment. The specific 5-HT_{2A/2C} agonist DOI also causes marked hyperthermia, suggesting the possibility that stimulation of 5-HT_{2A/2C} receptors might cause sympathetically mediated cutaneous vasoconstriction. The 5-HT_{2A} receptor antagonist ketanserin reversed the cutaneous vasoconstriction induced by DOI in rabbits and tail vasoconstriction and hyperthermia in rats. Furthermore, administration of the antipsychotic clozapine reverses hyperthermia and sympathetically mediated cutaneous vasoconstriction induced by MDMA in rabbits and rats. These mechanisms

Figure 1 Blood pressure increases caused by open-field novelty stress are modulated by serotonergic drugs in Sprague-Dawley rats, Wistar-Kyoto rats (WKY) and spontaneously hypertensive rats (SHR). Pretreatment with 0.5 mg/kg of the 5-HT_{1A} receptor partial agonist and dopamine D₂ receptor antagonist, buspirone, reduced the blood pressure increases in WKY and SHR. Pretreatment with 0.25 mg/kg of the 5-HT_{1A} receptor full agonist, 8-OH-DPAT, enhanced the blood pressure increase in Sprague Dawley rats, but reduced it in WKY, with no significant change in SHR. This same pattern of strain differences in responding was seen with pretreatment with the 5-HT_{1A} receptor partial agonist, MDL 73,005EF. The rats were placed in 90 cm open field while blood pressure was measured with radiotelemetry. For more data and details, see Van den Buuse and Wegener (2005).

support a role of serotonin mechanisms in stress-induced changes in body temperature. In addition, clozapine and ketanserin, by interactions with 5-HT receptors or by other serotonergic mechanisms, may be of therapeutic benefit in humans suffering from life-threatening hyperthermia such as that induced by ingestion of MDMA.

Conclusion

Serotonin is a widely distributed monoamine that has been involved in almost every function of the brain. Stress influences 5-HT activity, and this interaction could be involved in the development of stress-related illnesses, including depression and schizophrenia. Conversely, serotonergic drugs modulate activity of the HPA axis and physiological responses to stress. Thus, there is a direct reciprocal relationship between stress and activity of the serotonin system in the brain.

The Serotonin Transporter

The *5-HTT* Gene

Functional Polymorphisms of the *5-HTT* Gene

The Serotonin Transporter-Linked Polymorphic Region
and Stress

*Transcription
factor binding
site*

A consensus sequence within a gene, promoter, or regulatory region that is recognized and bound by a transcription factor that then regulates the transcription of that gene.

*Variable
number of
tandem repeats
(VNTR)*

A polymorphism within a DNA sequence that comprises varying numbers of repeating units. VNTRs can be microsatellites (usually repeat units of 2–8 bp) or minisatellites (more than 8 bp). VNTRs are hypermutable and often give rise to many alleles of different lengths.

Glossary

Enhancer

A short region of DNA that can be bound with proteins (such as transcription factors) to enhance transcription levels of genes. An enhancer does not necessarily have to be located close to the genes it affects, although some enhancers are found within intronic sequences.

*Messenger
RNA (mRNA)*

The primary sequence transcribed from the DNA template. mRNA has intronic sequences (i.e., sequences not represented in the transcript exiting the nucleus) removed by splicing and encodes the amino acid sequence of a protein.

*Poly-
adenylation*

The cleavage of mRNA and addition of 50–200 adenosine residues, a poly-A tail. Polyadenylation is an important post-transcriptional modification that ensures the appropriate termination of the molecule at the 3' end and helps in both the export of the mRNA from the nucleus and protection from exonucleases.

*Polyadenyla-
tion site*

The point of polyadenylation of newly transcribed mRNA.

*Serotonin
(5-hydroxy-
tryptamine,
5-HT)*

A protein present in many tissues, especially blood and nervous tissue; it stimulates a variety of smooth muscles and nerves and functions as a neurotransmitter.

*Single
nucleotide
polymorphisms
(SNPs)*

Single-base changes in a DNA sequence, for example a C to T substitution. SNPs can be found in the coding (exonic) and noncoding region (e.g., untranslated region, promoter, or intron) of a gene, and coding SNPs can be synonymous (no change in resultant amino acid) or non-synonymous (change in resultant amino acid).

Transcription

The synthesis of an RNA copy from a sequence of DNA; the first step in gene expression.

The Serotonin Transporter

The serotonin transporter (*5-HTT*) is important in the termination and modulation of serotonergic neurotransmission by sodium-dependent reuptake of serotonin into the presynaptic neuron, which thus terminates the synaptic actions of serotonin and recycles it into the neurotransmitter pool. The transporter is the site of action of a number of commonly used antidepressants, such as selective serotonin reuptake inhibitors (SSRIs), fluoxetine (ProzacTM), sertraline (ZoloftTM), and paroxetine (PaxilTM), and tricyclic antidepressants. A number of psychostimulants such as cocaine, methylphenidate, and MDMA (ecstasy) may also interact with *5-HTT*. For this reason, *5-HTT* has become one of the most widely studied genes in the field of behavior, especially in the context of psychiatric disorders such as depression, neuroticism, and suicidal behavior.

The *5-HTT* Gene

The gene encoding the *5-HTT* protein in humans has been mapped to the chromosomal location 17q11.2 and consists of 14 exons spanning approximately 38 kb. Several studies have focused on screening the genomic region for variation, and a number of polymorphisms have been characterized. Currently, at least 62 SNPs with frequency data within the gene, untranslated, or promoter region of *5-HTT* are listed in the Entrez SNP database (dbSNP). Most of these SNPs have not yet been investigated in the context of complex behavior, and any role they might have in regulation of the gene is still unknown.

Functional Polymorphisms of the *5-HTT* Gene

There are some regions within *5-HTT* that have been demonstrated to affect the expression of the gene.

Figure 1 Serotonin transporter gene (not to scale). a, Organization of the gene; b, promoter region; c, *5-HTTLPR* as either the S or L allele. In a, the coding exons are represented by diagonally marked boxes; noncoding exons are represented by dashed boxes. The position of the promoter (light grey) and intron 2 VNTR are shown. In b, the position of some postulated transcription factor binding sites are shown by arrows; the region of the 381-bp deletion is demonstrated by dashed lines, as is the position of the *5-HTTLPR* (dark grey box). In c, the light boxes represent the position of the two repeat units that are inserted in the L allele; the position of the A-G SNP is also shown.

The most common of these are described next (see [Figure 1](#)).

The Serotonin Transporter-Linked Polymorphic Region

One of the most documented variants within *5-HTT* is the serotonin transporter-linked polymorphic region (*5-HTTLPR*; [Figure 1c](#)), a polymorphic GC-rich repetitive element within the proximal 5' regulatory region. In humans (and indeed in primates), the *5-HTTLPR* is polymorphic, consisting of a variable number of 20- to 23-bp repeats. The *5-HTTLPR* exists as two common alleles: the short allele (S, 14 repeats) and the long allele (L, 16 repeats). There is evidence that this polymorphic region has functional significance; in JAR (human carcinoma) cells, the L allele confers higher activity than the S allele, whereas lymphoblastoid cells with the LL genotype have 1.4–1.7 times the amount of mRNA as SS or SL cells. Furthermore, the uptake of labeled serotonin in LL genotype cells is 1.9–2.2 times that in cells carrying one or two copies of the S variant. More recently, it has been shown that the *5-HTTLPR* gene actually exhibits a number of alleles of varying repeat numbers. Furthermore, the S and L alleles are themselves variable, so that,

although their length is similar, SNPs occur within their repeating units. In total, at least 14 alleles of varying length and sequence have been identified, four different S alleles (14-A to 14-D), six different L alleles (16-A to 16-F), and alleles consisting of 13, 15, 18, 19, 20, and 22 repeats. The longer alleles appear to exhibit a silencer effect on the gene, having lower activity than 14- and 16-repeat variants; however, these alleles are extremely rare and appear to be found in specific populations only, such as the 20-repeat allele in the Japanese population. Recently, it has been demonstrated that an A-G SNP (dbSNP reference number rs25531) within the sixth repeat of the *5-HTTLPR*, represented by the 14-D and 16-D alleles, creates a binding site for the transcription factor AP-2 that might affect the rate of transcription of the gene.

Recently however, the functional effect of the *5-HTTLPR* polymorphism has been called into question because *in vivo* experiments failed to find the same genotypic effect as that observed in cell lines. For example, the *5-HTTLPR* genotype has no effect on the 5-HTT binding of a serotonergic ligand, a measure of 5-HTT availability, in human brain. In other words, if the *5-HTTLPR* is driving differential

transcription, it has no eventual effect on *5-HTT* availability. Similarly, some experiments suggest that *5-HTT* binding in the brain does not differ by *5-HTTLPR* genotype. If these results are robust, then it may be that the expression patterns in cell-based assays do not accurately reflect the pattern of expression *in vivo*. Indeed, it has been shown that the regulation of the *5-HTT* depends on the presence of the substrate (serotonin, 5-HT) rather than on any genetically driven effect. This might be an indication of the many levels of complex regulation that genes are subject to *in vivo* that may not be accurately modeled by cell-line *in vitro* approaches; the functional effect of the *5-HTTLPR* observed in cells might be adapted by the complex intra- and extra-cellular factors that brain neurons are exposed to.

Intron 2 Variable Number of Tandem Repeats

Along with the *5-HTTLPR*, there are other proposed transcriptional regulatory regions within the *5-HTT*. One example is a VNTR within intron 2 that has been shown to have differential enhancer activities in the mouse embryo and in human embryonic stem (ES) cells (Figure 1a). The VNTR consists of 9–12 copies of a 16- or 17-bp repeat, the 12-repeat allele (STin12) having greater enhancer activity than the 10-repeat allele (STin10) in both model systems. This ability to regulate expression is cell-specific in humans, in that it is observed in ES cells but not HeLa cells. However, as in the case of the *5-HTTLPR*, the regulation is much more complex than the effect of repeat length; the VNTR does not comprise a succession of perfect repeats, rather there are seven varying repeat sequences and the differences between alleles is described by the deletion of specific repeat elements. The functional effect of the VNTR is regulated by at least two transcription factors – CTCF-binding factor (CTCF) and Y box binding protein (YB-1) – that bind to a sequence that is deleted in the nine-repeat allele (STin9). YB-1 is inhibitory, so binding to the VNTR results in decreased expression. However, the addition of YB-1 results in a release from inhibition of the STin9 VNTR in COS-7 cells because the inhibitory site is deleted. This effect is antagonized by CTCF and is not observed with either the STin10 or STin12.

This evidence suggests that *5-HTT* expression is differentially regulated by these two regions. However, little is known about their combined effect on transcription. The only evidence to date indicates that the expression of the gene is highest in lymphoblastoid cells having both *5-HTTLPR* L/L and STin12/STin12 genotypes. The expression is lowest in cells with at least one S and one STin10 allele. Based on previous evidence of higher expression of *5-HTT* with

LL- and STin12/STin12-compared to S- and STin10-containing genotypes, this finding could be said to fit an *a priori* hypothesis; but some replication is necessary before any firm conclusions on the synergistic action of the *5-HTTLPR* and intron 2 VNTR can be made.

Other Regulatory Elements

The transcriptional effect of the *5-HTTLPR* and intron 2 VNTR is further compounded by the observation of splicing variation within the 5' untranslated region, so that two alternative forms of *5-HTT* mRNA exist. Within the human brain and placenta, exon 1B is alternatively spliced and appears in transcripts to a varying degree, whereas exon 1A seems to be the principal transcription initiation point. This type of alternative splicing could help to specify cell-specific activity of the *5-HTT* and ensure appropriate levels of neurotransmission in different tissues. This tissue-specific splicing of 5' untranslated exons is also observed in the brain and gut in rats, indicating that it is a common mechanism of regulating protein expression. Furthermore, tissue-specific mRNA splicing might also be precipitated through multiple polyadenylation sites found in exon 14. This mechanism dictates alternate transcription stop sites that give rise to mRNA transcripts of varying length that, like alternative splicing of exons, might regulate tissue-specific expression. It has also been proposed that the structure of the *5-HTTLPR* is likely to result in a 381-bp deletion in the promoter region (Figure 1b) and that this deletion is present in 20–60% of genomic DNA derived from human brain and blood. Specific breakpoints suggest that the event is similar to V(D)J rearrangement often observed in antibody genes. This rearrangement results in looping out the 381-bp DNA sequence so that the two breakpoints are adjacent and are subsequently joined together, resulting in the deletion of the looped-out sequence.

The consequences of this deletion are not known, but it is suggested that the event is likely to be regulated by tissue- and *5-HTTLPR*-dependent mechanisms. However, this effect of mosaicism has yet to be consistently observed in multiple populations.

The Serotonin Transporter-Linked Polymorphic Region and Stress

The *5-HTT* has been implicated in the stress response because serotonin concentrations are increased within the synapse when under stress. Given that the *5-HTTLPR*, through gene-regulatory mechanisms, might affect the efficiency by which serotonin is

transported back in to presynaptic neuron, the *5-HTTLPR* is an ideal polymorphism candidate for studies of stress and its outcomes.

Animal studies have proven invaluable in this context because it is possible to accurately control both psychosocial and physiological effectors, unlike in humans. In Rhesus monkeys, there are variations in response to early rearing experience that are dependent on the primate *5-HTTLPR* genotype. Monkeys that possess an S allele have significantly lower cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA, a serotonin metabolite) concentrations than their homozygous L-allele counterparts. This suggests that serotonin reuptake is lowered in monkeys with an S allele, but the effect is specific to those who were peer-reared (early stressful environment) rather than parent-reared. No differential effect of genotype is seen between parent-reared monkeys. This suggests that early experience has some effect on the functioning of the serotonin system within primates and that the *5-HTTLPR* genotype becomes important only when stressful events are experienced. There also exists a knockout mouse for the serotonin transporter, a genetically manipulated mouse that is deficient in the *5-Htt* gene. Stressed mice that are heterozygous or homozygous for the knockout mutation (i.e., mice that have lower or negligible levels of 5-HTT) have a greater response to stress (measured as increased levels of stress hormone adrenocorticotrophic hormone, ACTH) than homozygous wild-type mice. The levels of ACTH are the same in knockout and wild-type mice when they are not stressed, again suggesting that it is the variability in 5-HTT density that participates in interindividual differences in stress response.

In humans, neuroimaging research suggests that individual differences in stress perception are mediated by genetic variations in the *5-HTTLPR*. Individuals with one or two copies of the S allele of the *5-HTTLPR* exhibit greater amygdala neuronal activity to fearful stimuli than individuals homozygous for the L allele. This suggests that the SS- and SL-genotype individuals respond to the same stressful event to a greater magnitude than the LL individuals. In addition, it has been demonstrated that there is a differential response to brain-derived neurotrophic factor (BDNF) by *5-HTTLPR* genotype. BDNF is involved in activating the stress response, so this suggests that variability in *5-HTT* may influence variability in other downstream molecular processes that 5-HTT is associated with. Some of the strongest evidence to date that the *5-HTTLPR* can modulate the human stress response comes from a longitudinal study of almost 1000 individuals from Dunedin, New Zealand, in which it was shown that variation in the *5-HTTLPR* can modify the effect of stress on

the outcome of depression. Stressful life events, such as the breakdown of a marriage or unemployment can lead to depression; however, this is not true for all individuals who experience stress. It was found that individuals who had the LL genotype of the *5-HTTLPR* were protected against the effects of stress in that their rates of depression were much lower than SS- and SL-genotype individuals with similar levels of stressful life events. This effect was seen whether the stress was experienced proximally (within the previous 5 years) or earlier (in childhood). The rates of depression in individuals who had not experienced stress were similar regardless of genotype. Consequently, evidence from these diverse sources suggests that variation in the *5-HTTLPR* can influence psychopathological reactions to stress and that it can account for some of the variability in individual response.

Sex Differences in Health and Disease
Sex Differences in Subjective Aspects of the Human Stress Response
Sex Differences in Physiological Aspects of the Human Stress Response

Glossary

Cortisol

A glucocorticoid hormone produced by the adrenal cortex. Cortisol exhibits a pronounced circadian rhythm and responds to a wide range of stressors. It has many physiological effects and virtually every single nucleated cell in the body has cortisol receptors. It is predominantly (90–95%) bound to binding proteins in blood; only 5–10% of the total plasma cortisol circulates as biologically active, unbound, free cortisol.

Hypothalamic-pituitary-adrenal (HPA) axis

A central regulatory and control system of the organism that connects the central nervous system with the endocrine system. Under stress, the hypothalamus secretes corticotropin releasing hormone (CRH), which provokes the release of adrenocorticotrophic hormone (ACTH) from the pituitary. ACTH triggers cortisol secretion from the adrenal cortex.

Lymphocytes

The functioning of the axis is controlled by several negative feedback loops.

White blood cells responsible for the specific responses of the immune system to antigens. Based on the tissue where the stem cells mature to the specific lymphocyte, they are called B cells or T cells. B cells mature in the bone marrow and form the cellular basis for the humoral immunity (e.g., antibody production), whereas thymus-derived T lymphocytes (e.g., T helper cells and T suppressor cells) represent the effector cells of the specific cellular immunity.

Sex steroids

Hormones produced in the gonads and, to a lesser degree, in the adrenal cortex. Estradiol and testosterone play major roles in the female and male reproductive system. In women, sex steroid concentrations show typical variations during the menstrual cycle. Sex steroids also influence the peripheral and central nervous system.

Sympathetic-adrenal-medullary (SAM) axis

Sympathetic nerves, originating in the central nervous system, stimulate the adrenal medulla, which in turn secretes epinephrine and norepinephrine. These catecholamines mobilize energy-producing mechanisms quickly and downregulate less important organ functions.

Sex Differences in Health and Disease

Men and women are at differential risks for a number of illnesses. This observation is reflected in the sex-specific prevalence rates for several diseases. Women suffer more often from autoimmune illnesses such as lupus erythematosus, multiple sclerosis, and neurodermatitis, whereas men are more prone to develop coronary heart diseases or infectious diseases. Concerning psychiatric disorders, women more often develop anxiety, depression, phobias, panic disorders,

or obsessive-compulsive disorder, whereas men more often are prone to antisocial behavior, substance abuse, or suicide. Although women consistently appear to report more physical and somatoform symptoms than men, the life expectancy for women is approximately 7 years longer than it is for men.

In addition to the clear sexual dimorphism with respect to certain diseases, sex differences exist in psychological and biological aspects of the human stress response. Investigation into sex-specific stress responses may help to reveal mechanisms that underlie somatic, psychosomatic, and psychiatric illnesses. Data showing that several diseases are associated with altered stress responses support this assumption.

On a behavioral level, psychiatric disorders such as depression and anxiety are interrelated with increased symptom reporting. On a physiological level, several of these disorders are accompanied by dysfunctional endocrine regulations. Major depression, susceptibility to infectious diseases, and cardiovascular problems seem to be associated with a hyperactive HPA axis, whereas autoimmune processes are associated more often with a hyporeactive HPA axis. The observation that (premenopausal) women (in contrast to men) seem to be protected from coronary heart disease parallels the finding that men show higher blood pressure changes and catecholamine increases under psychological stress. In addition to the described sex dimorphism with respect to disease and sex-specific stress responses in humans, it is generally accepted that exposure to stress can cause or intensify numerous diseases.

Thus, differences in health status may, at least in part, be related to sex differences in stress responses. Sex-specific stress responses do not seem to be epiphenomena of sex-specific prevalence rates of several disorders but, instead, appear to reflect causal links.

Sex Differences in Subjective Aspects of the Human Stress Response

Following Lazarus and Folkman, the extent of experienced stress is not determined by a situation or an event itself but is, instead, mediated by a three-phasic appraisal process. The importance or threat of the characteristics of a situation or an event is assessed in a primary appraisal loop. Simultaneously, in a secondary appraisal the amount of available coping capacity or resources is estimated. A final reappraisal determines the extent of experienced stress.

Several studies, ranging from everyday hassles to posttraumatic stress reactions, conclude that women subjectively experience more stress than men. A socio-cultural approach focusing on external environmental

factors emphasizes that women's lives are characterized more often by multiple social roles and lower socioeconomic status, which are both positively correlated with stressful life events. In addition to the finding that women experience more stress in everyday life, stress vulnerability and worry disposition also appear to be higher in women compared to men. This leads to the assumption that sex differences exist in people's readiness to perceive and appraise situations as stressful. This suggestion is supported by the finding that self-descriptions concerning self-esteem or self-confidence, self-efficacy, and sense of competence are slightly but consistently lower in women than in men. Although men repeatedly showed a more favorable locus of control and attribution style in questionnaire-derived studies, Miller and Kirsch concluded that data about sex differences in attributions, locus of control, and perceptions of control during stressful episodes remain inconsistent. Recent findings by Schulz and co-workers revealed that women's higher average scores in perceived stress, chance control orientation, stress-susceptibility, depressivity, and bodily complaints, as well as their lower scores in self-esteem and self-concept of ability, may be attributed to sex differences in worry disposition.

A higher sensitivity and attention to nonspecific stress symptoms appear to bring about more episodes of perceived stress in women. In contrast to women, men seem to be less sensitive in their perception of subtle bodily symptoms, and they are less prone to appraise bodily or emotional changes as significant. Concerning physical and somatoform symptoms, higher symptom reporting in women is described as a general phenomenon rather than one restricted to certain types of symptoms. This effect persists even after adjusting for psychiatric comorbidity such as depression and anxiety, disorders that are more prevalent in women and associated with increased reports of physical symptoms. The suggestion that women are more perceptive about emotions is supported by the finding that women outperform men at all ages in the encoding and decoding of emotions.

The differences in coping styles between men and women are small. Whereas women appear to prefer emotion-focused solutions including the greater use of social support and supportive networks, men focus more often on instrumental or problem-oriented coping. Reports on sex-specific effectiveness of coping strategies contradict the former notion that women's coping strategies could be inadequate or less effective for alleviating distress.

Investigations of perceived stressfulness after confrontation with various standardized laboratory

stressors repeatedly led to similar reports of feelings of distress in men and women. Whereas performance in laboratory stress tests was not associated with sex, women tend to judge their own efforts and performances as poorer than men do.

The assessment of subjective aspects of the human stress response is always based on self-reports measured by standardized questionnaires, interviews (structured or half-structured), and open (unstructured) reports. Therefore, it should be considered that sex-related response differences to stress could also reflect sex-specific biases in the willingness (or capability) to report distress.

Sex Differences in Physiological Aspects of the Human Stress Response

Different regulatory systems of the human body are activated by stress. Endocrine stress-responsive systems such as the HPA and SAM axes help the organism adapt to increased demands and maintain homeostasis after challenge. In addition to hormonal responses, stress also provokes changes in cardiovascular and immunological parameters.

Hypothalamic-Pituitary-Adrenal Axis

Investigation of HPA axis responses to different types of stressors revealed that physical exercise ($>70\%$ $\text{VO}_{2\text{max}}$) and psychological challenges are potent activators of the HPA axis. Whereas the majority of studies did not reveal any sex differences in response to physical exercise, confrontation with psychosocial stimuli leads to higher adrenocorticotrophic hormone (ACTH) and free cortisol levels in adult men than in women. This sex difference is conserved after menopause and in elderly individuals. Total cortisol secretion, however, does not differ between sexes in young adults. Although men and women show similar total cortisol responses after stress, a sexual dimorphism exists in the amount of bioavailable free cortisol, an observation calling for simultaneous measurements of total and free cortisol levels. These findings can, at least in part, be explained by greater ACTH pulses in men as well as by the higher sensitivity to ACTH of the adrenal cortex in women.

Observed sex differences in HPA axis stress responses may be due to sexual dimorphisms in brain functions and circulating sex steroid and corticosteroid-binding globulin (CGB) levels. Prime candidates for explaining sex differences in HPA axis stress responsiveness are the gonadal steroids. Among them, estradiol seems to exert modulating effects on HPA axis functioning, including HPA axis responsiveness and sensitivity to glucocorticoid negative feedback.

Animal studies consistently revealed that estradiol has a strong stimulatory influence on HPA axis functioning with modulatory effects on mineralocorticoid and glucocorticoid receptors.

Although human data are more contradictory than evidence from animal literature, gonadal steroids also seem to exert important modulatory effects on HPA axis functioning in humans. In a series of studies from our laboratory, free cortisol responses systematically varied as a function of menstrual-cycle phase. Women in the luteal phase show free cortisol stress responses comparable to men, whereas women in the follicular phase and women taking oral contraceptives have significantly lower free cortisol responses. Although the total plasma cortisol net stress responses differ neither between men and women nor between different menstrual-cycle phases, the absolute levels are elevated in women with oral contraceptive use. A short-term estradiol treatment potentiated HPA axis responses to acute psychosocial stress in young men. Furthermore, a 2-week estradiol substitution seemed to diminish the endocrine response of postmenopausal women to exogenous corticotropin releasing hormone (CRH) after dexamethasone premedication, as observed in women with and without short-term estradiol treatment. In addition, a comparison with a third group of premenopausal women indicates that the feedback sensitivity of elderly estradiol-treated women approximates the endocrine response of premenopausal (untreated) women. However, this treatment did not change the acute HPA axis stress responses to psychosocial stress (Trier Social Stress Test). In sum, it should be acknowledged that there is still a paucity of data on the effects of gonadal steroids on the regulation of the human HPA (and SAM) axis. There is a definite need for future in-depth studies on these issues.

Sympathetic-Adrenal-Medullary Axis

Studies investigating SAM axis responses to stress showed that stress-induced epinephrine increases are higher in men than in women, suggesting that men are more sensitive to sympathetic stimulation via emotional arousal. In contrast, no sex effects are reported for norepinephrine concentrations. However, contradictory results also exist.

Reproductive hormones appear to have a significant impact on catecholamine stress responses. This assumption is confirmed first by findings of altered catecholamine levels throughout the menstrual cycle with enhanced epinephrine levels during the luteal phase. Second, comparisons between pre- and postmenopausal women revealed that stress-related epinephrine responses are increased in postmenopausal women

and that estradiol treatment reduced catecholamine reactivity to stress. Third, short-time estradiol administration modulates catecholamine reactivity in healthy young men, although the direction of the effect remains contradictory. Although the majority of studies point to an estradiol-mediated reduction in SAM axis responses to laboratory stressors, a few carefully conducted studies show sex steroids to have no or a stimulating effect.

Cardiovascular Responses

In a meta-analysis, Stoney and coworkers summarized sex differences in stress-related heart-rate and blood pressure changes. They concluded that women have higher heart rates at rest as well as slightly larger increases during challenge, whereas men exhibit higher systolic blood pressure changes. Allen and colleagues also showed higher heart-rate increases in women and higher blood pressure changes in men after confrontation with various laboratory stress tasks, supporting the conclusion that women are more likely to be cardiac reactors and men are more prone to be vascular reactors. We aggregated heart-rate responses across five different studies in healthy children and in younger and elderly adults. Accordingly, enhanced heart-rate stress reactivity can be observed in girls and young adult females compared to boys and young adult men. However, in older men and women peak heart-rate responses are comparable, with only men returning to prestressor baselines during recovery.

Although the data are inconsistent, reports of blood pressure changes as a function of menstrual-cycle phase point to sex steroids having an impact on cardiovascular functioning. The fact that coronary heart disease morbidity and mortality rates increase in women after menopause, a time characterized by the marked decrease of reproductive hormones, confirms the protective role of sex steroids. In line with this idea, reports show that postmenopausal women have a higher cardiovascular responsiveness than premenopausal women.

Whereas postmenopausal estrogen use predominantly reduces the risk of coronary heart disease in women, exogenous estrogen use in clinical trials or hormonal replacement therapy studies do not consistently confirm the protective role of estrogens. The apparently conflicting results of exogenous estrogen use on cardiovascular functioning could be explained by a dual action of estrogens. Estrogens may increase the risk of thrombo-embolic events due to an adverse influence on coagulation, and simultaneously they may help to prevent atherogenic events through favorably changed lipid and lipoprotein levels.

Immunological Responses

In general, immunological activity appears to be higher in women than in men. Whereas levels of circulating immunoglobulins are higher and antibody responses to a variety of pathogens are larger in females, sex differences in cell-mediated immunity can vary depending on the immunological parameter studied. Sex differences in basal immunological functioning may result from the stimulation of lymphoid tissues by sex steroids. In general, estrogens appear to suppress T-cell-dependent immune function, but can increase antibody reactivity to antigens. Testosterone (and other androgens) has an immunosuppressive effect and increases susceptibility to infection, although it may help to prevent the development of autoimmune processes. In sum, sex hormones have been shown to modulate a large variety of mechanisms involved in the immune response. Evidence is accumulating that shows that estrogenic and androgenic actions on cells can be mediated not only through classical intracellular receptors but also through membrane receptors on cell surfaces of compounds of the immune system. Wunderlich and coworkers investigated possible cross-talk of nongenomic testosterone signaling with other genotropic signaling pathways in the rat. Furthermore, in addition to direct receptor-mediated influences, indirect effects on immunological functioning and disease processes may be exerted by sex-steroid-induced changes in other biological systems that are interrelated with the regulation of the immune system. For example, the androgenic steroid hormone dehydroepiandrosterone sulfate (DHEAS) was recently shown to inhibit apoptosis in human peripheral blood lymphocytes through a mechanism independent of either androgen or estrogen receptors.

Although there is a voluminous literature showing the impact of acute laboratory stress on rapid immune cell changes, sexual dimorphisms in immune responses to stress in humans have not been extensively examined and the reported results remain contradictory. Whereas Kiecolt-Glaser and colleagues found that women are more likely to elicit immunological changes after controversial discussions with their husbands, as reflected by a summary immune change score (based on killer cell lysis, blastogenic responses to two mitogens, the proliferative response to a monoclonal antibody to the T₃ receptor, percentage of macrophages, and number of T lymphocytes), Scanlan and coworkers concluded that immunological parameters appear to be more affected by psychosocial stressors (hassles and caregiving) in men than in women. Recently, Pehlivanoglu and colleagues observed a shift from cellular to humoral immunity (only) in men and showed evidence that acute stress

may cause different immunological changes across the female menstrual cycle. In addition to these sexual dimorphisms, the use of oral contraceptives (OC) can also alter stress-induced immune responses in women. Furthermore, sex and OC intake may exert differential effects on the immune system by modulating glucocorticoid sensitivity of pro-inflammatory cytokine production.

In sum, immune functions at rest and under stress differ significantly between men and women, apparently due to sex-related differences in sex steroid levels.

Prolactin

A hormone secreted by the anterior pituitary gland whose function, among others, is to stimulate the growth of milk-secreting glands in the breast in preparation for, or maintenance of, lactation.

Psychophysiological disorders

Disorders such as chronic fatigue syndrome, irritable bowel syndrome, and fibromyalgia, which are stress-related body symptoms

Introduction

Gender Differences in Depression and Stress Syndromes
Sex Steroids
Stress
Conclusion

Glossary

<i>Circadian rhythms</i>	Twenty-four-hour sleep–wake cycles.
<i>Estrous cycles</i>	Cyclic sexual receptivity in female animals that is accompanied by specific hormonal periodicity and that lays the groundwork for impregnation.
<i>Genomic effects</i>	Direct effects on DNA in cell nuclei.
<i>Growth hormone</i>	A polypeptide hormone secreted by the anterior lobe of the pituitary gland that promotes tissue and skeletal growth and influences the metabolism of proteins, carbohydrates, and lipids.
<i>Hypothalamic-pituitary-adrenal axis</i>	The hormonal circuit from the hypothalamus to the anterior pituitary gland to the adrenal gland and back to the hypothalamus.
<i>Hypothalamic-pituitary-gonadal axis</i>	The hormonal circuit from the hypothalamus to the anterior pituitary gland to the ovaries or testes and back to the hypothalamus.
<i>Hypothalamic-pituitary-thyroid axis</i>	The hormonal circuit from the hypothalamus to the anterior pituitary gland to the thyroid gland and back to the hypothalamus.
<i>Melatonin</i>	A hormone that is secreted by the pineal gland and that regulates the onset and timing of sleep.
<i>Neurotransmitters</i>	Chemical messengers that cross the gap between neurons to either excite or inhibit the neighboring neuron.
<i>Posttraumatic stress syndrome</i>	A set of psychiatric symptoms that develop as a reaction to a traumatic event.

Introduction

From a physiological point of view, both depression and anxiety are the product of complex alterations of the hypothalamic-pituitary-thyroid axis, of prolactin, growth hormone, and melatonin irregularity, of sleep, activity, appetite, and temperature disturbance, of hypothalamic-pituitary-gonadal axis and hypothalamic-pituitary-adrenal axis deregulation, and of multiple neurotransmitter disequilibrium. Given the gender ratio of the prevalence of depression and anxiety and the generally accepted role that stressful life events and powerful emotions play in the precipitation of mood disorders, this article focuses on the effects of ovarian hormones on the body's response to stress.

Gender Differences in Depression and Stress Syndromes

Women are more susceptible than men to all forms of depression. Even in bipolar affective (manic-depressive) illness, in which the gender prevalence is equal, the frequency of depressive episodes is higher in women. Chronic, subthreshold depression (dysthymia) and episodic major depressive disorder are at least twice as common in women as they are in men. These sex differences have been replicated in all major door-to-door epidemiological surveys and in treatment-seeking population samples from around the world, with the exception of reports from countries where women are known to have reduced access to medical services. Strikingly, this sex ratio does not emerge until adolescence, when gonadal hormones are activated. Before puberty, depressive episodes are as frequent in boys as they are in girls.

Anxiety may be a symptom of a depressive episode or it may constitute the major component of a variety

of anxiety syndromes such as posttraumatic stress disorder (PTSD), phobia, panic disorder, agoraphobia, obsessive-compulsive disorder, and generalized anxiety. With the exception of obsessive-compulsive disorder, in which the gender ratio is equal, adult women are more susceptible than men to all the preceding *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-defined syndromes. As in depression, the sex differences in most forms of anxiety emerge only after adolescence.

The aftermath of stressful life events may be experienced in the psychological realm, as in PTSD, or primarily in the somatic realm, as in the various psychophysiological disorders. Both forms are more prevalent in women. When exposed to a major trauma, approximately twice as many women as men develop PTSD, and women make up about 85% of PTSD sufferers whose symptoms last for over 1 year after exposure. After the World Trade Center attack, gender differences in PTSD could be explained by differences in marital status (more common among women living alone without a permanent relationship) and education (more common among women with relatively little education and low income), but significantly more women experienced major depression and significantly more men were diagnosed with a substance abuse disorder. These differences persisted after adjustment for demographic variables.

Both depression and anxiety are more severe and more frequent during the premenstrual, postpartum, and menopausal periods of women's lives. An example of experimentally elicited menstrual phase vulnerability is the Van Goozen et al. report of a study involving 58 healthy women. Deliberately arranged anger provocation evoked most emotionality in those women who were premenstrual at the time of the experiment. Bloch et al. used an analogous design to investigate susceptibility to depression in response to exogenous estrogen and progesterone among women with a history of postpartum depression. Five of eight women with a history of postpartum depression, and none of the control women, with no psychiatric history, developed significant mood symptoms during hypogonadism induced via administration of a gonadotropin releasing-hormone agonist.

In summary, depressive and anxious states, as well as stress-provoked somatic conditions, are two to three times as common in women as in men, but there is no consistent sex difference in their prevalence prior to puberty. In women, symptom severity and frequency are associated with times in the reproductive cycle when the circulating level of ovarian hormones (estrogens and progestins) are falling.

Sex Steroids

Male-Female Differences

Gender differences in illness prevalence can result from a combination of inborn, learned, and socially imposed factors, but what distinguishes the sexes during fetal development are sex-specific hormones that exert powerful effects on the fetal brain and contribute to its sexual differentiation. While the hormonal milieu does not differ appreciably for boys and girls between birth and puberty, their brains are sexually differentiated from early gestation. The dramatic hormonal changes at puberty, superimposed on a dozen or more years of differential sex role experience, exert a profound effect on the adolescent brain. In addition to median levels of sex steroids, what also differs after puberty (and this may turn out to be the crucial difference) is that only women undergo menstrual cycles. Both sexes are subject to pulsatile changes in hormone level and circadian fluctuations, but the monthly repetitive hormonal cycles interrupted by pregnancy are unique to women. It is not until very old age, when the testes stop producing testosterone, that the hormonal environment of the male brain and that of the female brain once again approach the par that existed prior to puberty. Even then, receptor densities for the various hormone agonists and their site specificity remain gender distinct.

These biological differences may play out in the context of differential exposure to social and/or psychological stress. It has been proposed that women may experience a greater frequency of stressful life events than men. Alternatively, women may be more likely than men to interpret life events as stressful. However, a recent twin study by Kendler et al. revealed that men and women were equally likely to experience an episode of major depression associated with a major life event, although the categories of significant events differed between the sexes (i.e., interpersonal events were more relevant to women; work problems were more relevant to men).

In summary, although exposure to the impact of different experiences modulates the internal cascade of neurochemical events in which sex hormones play such a crucial part, neuroendocrine differences and their sex-specific rhythms are arguably central to male-female differences in the vulnerability to depression and anxiety. Hormones determine how the male and female brain processes the experience to which it is exposed, in particular, how it differentially responds to stressful experience and powerful emotions.

Sex Steroids and Neurotransmitter Systems

Sex steroids operate through genomic effects on neurotransmitter receptor protein or through direct membrane effects on the electrical firing rate of neurotransmitter-secreting cells. The genomic effect is relatively slow (minutes to hours); the membrane effect is rapid (microseconds to minutes).

It is well recognized that the serotonergic system is important in the maintenance of mood. The effectiveness of selective serotonin reuptake inhibitors (SSRIs) in the treatment of both depression and anxiety has highlighted the serotonin system. Estrogens exert multiple effects on serotonin function, many of which are site specific. In the amygdala, a key brain structure involved in the mediation of environmental stress, estrogens increase serotonin turnover. Estrogens increase the density of serotonin 5-hydroxytryptamine 2A (5HT_{2A}) receptors in rat cerebral cortex and nucleus accumbens. They decrease 5HT_{1A} mRNA in the medial amygdala, piriform cortex, and perirhinal cortex, suggesting a possible pathway through which mood and memory are modulated. Throughout the brain, estrogens increase the rate of degradation of monoamine oxidase, which, in turn, leads to increased brain availability of both serotonin and catecholamines. The interaction between estrogen and the serotonin system may have clinical implications: there is recent evidence that SSRIs are effective in reducing vasomotor symptoms associated with estrogen decline during menopause, and estrogen therapies may hold promise in management of hormone-dependent psychiatric conditions, including postpartum depression. Finally, there is some evidence that concurrent estrogen therapy may augment or accelerate response to SSRIs in women.

Estrogen-responsive and progesterone-responsive neurons use the inhibitory γ -aminobutyric acid (GABA) as a transmitter, producing an anxiolytic affect. Estrogen also induces choline acetyltransferase and potentiates excitatory amino acids such as glutamate and aspartate. The estrogen effect on the dopaminergic system is complex and phasic, causing alterations in pre- and postsynaptic dopamine receptors and differential distribution of the isoforms of the dopamine D₂ receptor messenger RNA. More specific to stress and depression, estrogens block both the synthesis and the depletion of catecholamines, including norepinephrine. Norepinephrine plays a major role in the autonomic stress response. Estrogens work via endogenous opiate peptides to exert an activating influence on the autonomic sympathetic response to stress, which results in vasoconstriction, quickened heartbeat, and sweating, common symptoms of anxiety.

In summary, ovarian hormones exert multiple, complex effects on neurotransmitter systems understood to be involved in depression and anxiety syndromes.

Effects on Membrane Stability

Because of their mainly activational influences, estrogens are proconvulsants in susceptible individuals, decreasing seizure threshold and increasing the magnitude of seizure activity. In experimental animals, this appears to be a direct consequence of depolarization of cellular membranes. Progesterone, on the other hand, raises the seizure threshold, an effect opposite to that of estrogen and probably responsible for catamenial or premenstrual epilepsy, when progesterone levels drop. Seizure activity (e.g., electric shock treatment) has been known for a very long time to ameliorate depressive mood.

In summary, the net effect of progesterone is to reduce anxiety but to deepen depression. The opposite is true for estrogen: levels of circulating estrogens correlate with increased alertness in animals, reduced distractibility, and shorter reaction times. The two hormones maintain a balance or homeostasis that, when disturbed, can tip a vulnerable person in the direction of mental states that are diagnosed as depression or anxiety.

Other Variables

Estrogens increase blood flow to the brain and within the brain, which speeds metabolism and increases the general efficiency of neural networks and increases the effectiveness of drug delivery. Estrogens stimulate glucose transport and metabolism, promoting the ability of neuronal networks to perform their work.

Neuronal responsiveness to steroid stimulation results from both genetic and membrane effects at multiply distributed sites involving large neural circuitry. Network effects may differ depending on the particular configuration of a specific circuit. Hormonal effects on neural network properties appear to be state dependent. In other words, effects may differ widely depending on the light-dark cycle, the sleep cycle, the activity cycle, the glucose level, the noise level, the presence or absence of an animal of the opposite sex, the general stress level, and the specific type of stressor.

Genomic Effects

Among the many genes suspected to come under the influence of estrogens are those responsible for neuronal development, migration, growth, and survival, for dendritic spine formation and density, and for antioxidant activity, synaptic plasticity,

neurodegeneration, and apoptosis secondary to glucose deprivation or other toxic event.

Steroid hormones are important epigenetic regulators. In a tissue-specific manner, they control the dosage effects of genes. They can turn genes off and on. They bind to their own receptors, a family of DNA-binding proteins located within the cell nucleus. The human estrogen receptor (ER- α) has been characterized both at the cDNA level and at the genomic level. It is transcribed from three different promoter regions. The expression of these three ER- α mRNAs appears to be regulated in a tissue-specific and, perhaps, age-specific way.

ER- α is sparsely distributed in key cognitive regions. This made it difficult to understand why estrogen replacement therapy sometimes improved cognitive functions until the recent discovery of a new estrogen receptor (ER- β), localized in brain regions associated with learning, memory, and emotion.

Once estrogen enters the cell nucleus and binds to the ER expressed in that cell, a conformational change takes place. The receptor's DNA binding domain is exposed and attaches to specific sequences of nucleotides in the nuclear DNA, thus regulating the transcription of a target gene. Adapter proteins or other transcription factors, which are cell specific, modulate the strength of the activation of the gene. Genetic transcription is one way in which estrogens modify the structure and function of brain cells.

Membrane Receptors

Estrogen also produces nongenomic effects by binding to neuronal membrane receptors. This effect is rapid, with a latency of seconds to minutes, and disappears quickly. Estrogen effects on dendritic spines in the CA1 region of the hippocampus are a good example of a rapid response. Estrogen given to an ovariectomized rat produces an increase in the number of spines on apical dendrites of CA1 pyramidal neurons. Cyclic changes in spine density can be seen throughout the estrus cycle of rats, suggesting the formation and destruction of synapses in quick time, presumably, therefore, mediated via membrane receptors. One mechanism through which dendritic spine density is increased is neurotrophin brain-derived neurotrophic factor (BDNF). Estradiol downregulates BDNF in cultured hippocampal neurons within 24 h of exposure. This increases excitatory tone in pyramidal neurons, which may lead to as much as a twofold increase in dendritic spine density.

In summary, estrogens, by a variety of means, help to increase neuronal connections. If nerve impairment occurs, they foster repair and delay or prevent secondary atrophy.

Stress

The Stress Response

The human organism has evolved an elaborate mechanism for dealing with perceived threat. Cortisol, epinephrine, and norepinephrine are automatically released, mobilizing the necessary energy for fight or flight. This primarily involves the limbic-hypothalamic-pituitary-adrenal-gonadal-thyroid axis. The integration of external stimuli converges on the medial parvocellular division of the paraventricular nucleus of the hypothalamus (mpPVN), which secretes corticotropin-releasing hormone (CRH). This hormone binds to its receptors in the anterior pituitary, stimulating adrenocorticotrophic hormone (ACTH)-secreting cells. ACTH is released into the circulation and, in the adrenal cortex, activates the synthesis and release of glucocorticoids whose many actions are mediated via specialized receptors affecting and regulating genes throughout the body. At the same time, stress leads to the modulation of the secretion of thyroid-releasing hormone and gonadal-releasing hormone from the hypothalamus with subsequent downstream effects on the thyroid and the gonads. Appetite and the need for sleep are suppressed. Growth stops. The overall result is that the organism is prepared to meet the perceived threat.

A large part of the brain is devoted to coping with stress. The amygdala is also placed on alert and activates the hypothalamic-pituitary-adrenal (HPA) axis. The prefrontal cortex is involved in assessing the danger and putting a halt to the stress response when the danger is past.

Men and women show differential HPA axis responses to psychosocial stress, with women of reproductive age showing less pronounced HPA axis responses to stress than men of the same age. However, this response varies with menstrual cycle phase and menopausal status, suggesting interactions between the HPA axis and gonadal hormones.

Termination of the Stress Response

The level and duration of glucocorticoid activity must be adequate to the organism's need to deal effectively with the perceived stressor. Glucocorticoids (helped along by excitatory amino acids) are, however, potentially harmful and may cause cell death through the promotion of apoptosis. A mechanism needs to be in place for their rapid elimination. Otherwise, what is adaptive becomes, under conditions of severe or ongoing stress, an agent of pathological change. Hippocampal neurons, particularly rich in steroid receptors, are exquisitely vulnerable to glucocorticoid-induced atrophy.

Many negative feedback loops exist within the stress activation system, which effectively puts a stop to the glucocorticoid stress response once it is no longer needed. Besides inhibition of the amygdala by the thinking brain, the prefrontal cortex, mounting concentrations of cortisol in the brain automatically shut off production of CRH. Sex steroids do the same. The rapidity of both stress activation and stress termination is affected by the circadian rhythm in plasma glucocorticoid levels, being most responsive when steroid levels are at their lowest, in the late evening in diurnal animals.

Stress Response Termination in Depression

Efficient termination of the stress response may be impaired in depression. For instance, the left prefrontal cortex has been shown in functional imaging studies to be impaired in major depression. As mentioned previously, depression and stress have long been associated. Adverse life events trigger depressive episodes, and depression itself constitutes an ongoing stressor to the organism. The experience of depression is one that precludes pleasure and hope, prevents sleep, and diminishes appetite, metabolic activity, autonomic function, neuroendocrine processes, growth, and reproduction.

There has been a long tradition of cortisol measurement in depressive states, culminating in the mid-1970s with the introduction of the Dexamethasone Suppression Test (DST) as a diagnostic test. The assumption was that suppression would be deficient in depression, and this has turned out to be true in at least some forms of depression.

This fact may explain some of the cognitive impairment that accompanies depression when glucocorticoid levels remain high and result in atrophy of hippocampal cells. Gonadal steroid receptors, with variations from one time period to another, are also expressed in the hippocampus. In animal experiments, androgens have been shown to downregulate glucocorticoid receptors in the hippocampus. Estrogens have also been reported to protect against glucocorticoid-induced hippocampal atrophy. Although both androgens and estrogens are potentially protective, both female rats and female monkeys undergoing various forms of experimentally induced stress fare better than their male counterparts with respect to secondary hippocampal damage.

In summary, a sustained stress response produces hippocampal degeneration and atrophy of apical dendrites of hippocampal pyramidal neurons. The interaction among glucocorticoids, neuronal growth factors, neurotransmitters, and sex steroids is complex and still in the process of clarification. Acute responses to stress, when prolonged, cause damage.

Conclusion

It would appear from animal work that women might have an advantage over men with respect to neuronal protection in the face of stress. Why, then, are they more prone than men to depression and anxiety?

The integrity of circadian rhythms and sleep-wake cycles seems to play a part in depression. People with depression feel worse in the morning than in the evening. They cannot sleep. They wake early. Resynchronizing the sleep cycle is an effective treatment for depression. The stress response cascade is modulated by circadian rhythm, and estrogens appear to be important circadian pacemakers. Is it possible that the monthly periodicity of ovarian hormones destabilizes these regular daily rhythms and thus contributes to women's special vulnerability to depression? The monthly cycling may sensitize target receptors and may in fact kindle these mechanisms in such a way that high circulating levels of ovarian hormones are needed to maintain equilibrium. This means that vulnerability to stress-related episodic depression and anxiety is heightened during periods of relative hormone decline.

That being said, it is also important to keep in mind that the physiological stress response cascade and its sequelae may be triggered by emotions other than fear of perceived threat. It may be precipitated by strong feelings of many sorts, such as frustration, empathy, or guilt, for instance, and these feelings may be relatively ubiquitous in women, prone as women are to relatively close interpersonal attachments and larger social networks when compared to men. Nurturant proclivities may be mediated by prolactin, produced in the anterior pituitary. The activities of this hormone (more active in women) may help to explain the sex ratio of adult depressive disorders.

In summary, women are more prone than men to suffer from anxiety and depression in their many forms. The mechanisms involved may reflect a tendency to hyperarousal or prolonged arousal when responding to a stressor. The sex differences may be due to relative inefficiency in turning off the stress signal, perhaps resulting from monthly kindling by fluctuations in ovarian hormones or, alternatively, from a relatively wider range of stimuli eliciting the stress response in women.

Glossary

<i>Demasculinization</i>	Loss or attenuation of male-typical traits.
<i>Feminization</i>	Enhancement of female-typical traits.
<i>Maternal effects</i>	Mothers' control over offspring development.
<i>Prenatal stress</i>	When stressors acting on pregnant females result in significant consequences for the offspring during fetal development and/or later in life.
<i>Social environment</i>	Part of an individual's environment that is constituted by other members of the same species.
<i>Social stress</i>	Stress due to members of the same species.

Prenatal Stress

Internal and external stressors constantly challenge organisms. Animals and humans respond to environmental challenge by activating a variety of coping systems (e.g., the hypothalamic-pituitary-adrenocortical [HPA] and the sympathetico-adrenomedullary [SAM] system). These systems are activated to maintain the internal milieu within a normal physiological range (i.e., homeostasis). This is crucial for normal pre- and postnatal development. The activation of the HPA axis results in an elevated secretion of glucocorticoids (e.g., cortisol, corticosterone), while the activation of the SAM axis causes an increase in serum catecholamine concentrations (e.g., epinephrine, norepinephrine). If stressors act on a pregnant female, concentrations of maternal hormones will change. Because the internal environment of the pregnant animal constitutes much of the embryo's external environment, it is reasonable to suggest that the former may affect fetal development. It is well-known that stressors acting on the organism during the pre- and/or perinatal phase can have distinct and long-term effects on behavior, reproductive functions, and the immune as well as the neuroendocrine and autonomic systems. For example, it has been reported numerous times that stress applied to pregnant rats results in demasculinization (i.e., lower levels of copulatory behavior) and feminization (i.e., higher levels of lordosis behavior, a female-typical sexual behavior) of male offspring compared to sons of nonstressed mothers.

Nonsocial versus Social Stressors

In most experimental studies on the effects of early stress, pregnant nonhuman mammals were subjected to nonsocial stressors (e.g., regimens of heat, bright light, or restraint). However, most of these stressors do not exist in the natural world of the animals and so it is questionable whether they represent ecologically relevant stimuli.

In their natural habitat, animals have to cope with a variety of social stressors that are indicative of their ecological niche. They have to adjust to stressors in the physical aspect of their environment (e.g., inclement weather) as well as in the biotic world that surrounds them (e.g., predators, food shortage). A major part of an individual's biotic environment consists of other members of the same species, which can be defined as his or her social world. In fact, a majority of human and nonhuman animals' daily expectations, motivations, and behaviors are directed to encounters with conspecifics. On the one hand, this social world can support good welfare and health (e.g., through the effects of social support). On the other hand, it can result in severe degrees of stress that can eventually

lead to disease and even death (e.g., in the case of social defeat, social instability, or crowding). Thus, the social environment can represent a most effective stressor, and during pregnancy it can be crucial for the development of the offspring as well.

A Study in Guinea Pigs

In nonhuman mammals, studies on prenatal social influences on offspring development have been conducted in several species, including mice, rats, bank voles, squirrel monkeys, and pigs. The most comprehensive data so far have come from guinea pigs. In this species social stimuli have widespread neuroendocrine effects, and it is argued that this species is well suited for the study of socioendocrine effects throughout the life span and can be a valuable complement to nonhuman primate research in this area. Guinea pigs in prenatal stress research were kept in two different social situations: in a stable and an unstable social environment. In the stable social environment, the group composition (one male, five females) was kept constant; in the unstable social environment, two females from different groups were exchanged every third day. The instability of the social environment during pregnancy and lactation alters the development of the offspring in a sex-specific fashion (for a summary see [Table 1](#)).

Table 1 Summary of the effects of early social stress in guinea pigs^a

	Females	Males
Behavior	SF masculinized	SM infantilized
Body weight	SF = CF	SM = CM
Serum cortisol	SF = CF	SM delayed decrease with age
Serum testosterone	SF >>>> CF	SM = CM
Adrenal TH	SF >>>> CF	SM <<<< CM
Adrenal weight	SF >>>> CF	SM = CM
Leucocytes	SF << CF	SM = CM
Granulocytes	SF << CF	SM = CM
ER- α ARC	SF >>>> CF	SM = CM
ER- α MPOA	SF > CF	SM = CM
ER- α CA1	SF >> CF	SM << CM
AR ARC	SF >>>> CF	SM <<<< CM
AR MPOA	SF >>>> CF	SM << CM
AR CA1	SF >> CF	SM = CM

^aCF, adult control females; SF, early stressed females; CM, control males; SM, early stressed males; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosteronesulfate; adrenal TH, activities of the adrenal tyrosine hydroxylase; ER- α , estrogen receptor- α , neurons with nuclear staining; ARC, arcuate nucleus; MPOA, medial preoptic area of the hypothalamus; CA1, pyramidal cell layer of Ammon's horn of the hippocampus; AR, androgen receptor, neurons with nuclear staining. Statistics: </>, $p < 0.1$; <</>>, $p < 0.05$; <<</>>>, $p < 0.01$; <<<</>>>>, $p < 0.001$; =, $p > 0.1$ (for details see text).

Effects on the Development of the Daughters

Daughters whose mothers lived in an unstable social environment show a most conspicuous behavioral masculinization: they display significantly higher amounts of male-typical courtship and play behavior later in life than daughters whose mothers lived in a stable social environment. The behavioral masculinization of prenatally stressed adult female guinea pigs is accompanied by increased testosterone concentrations. (Even though testosterone is mainly found in male mammals, produced predominantly by the testis, it can also be found in females. In female mammals, testosterone is secreted by the ovaries as well as the adrenal cortex; however, in much lower concentrations compared to males.) Furthermore, daughters whose mothers lived in an unstable social environment show elevated activities of the SAM system compared to daughters whose mothers have lived in a stable social environment. This activation of the SAM system is indicated by greater adrenal tyrosine hydroxylase activity. This enzyme catalyzes the rate-limiting step of the catecholamine (e.g., epinephrine, norepinephrine) biosynthesis. Finally, daughters whose mothers lived in an unstable social environment show a male-typical expression pattern of androgen receptors (ARs) in parts of the limbic system, that is, significantly more neurons with nuclear staining are present in the medial preoptic area (MPOA) and the arcuate nucleus (ARC) of the hypothalamus. Furthermore, an upregulation of ARs in the CA1 region of the hippocampus and of estrogen receptor- α (ER- α) in the MPOA, ARC, and CA1 is found in daughters whose mothers lived in an unstable social environment. The MPOA plays an essential role in the control of many aspects of sexual behavior, such as masculine behavior and sexual preference; the ARC is important for the regulation of gonadotropin-releasing factors; and the hippocampus is involved in the regulation of vegetative functions as well as in learning and memory.

Effects on the Development of the Sons

Different effects are found in early stressed males. Sons whose mothers lived in an unstable social environment display behavioral patterns, that are usually shown only by very young male guinea pigs (e.g., resting with bodily contact) more frequently and until an older age than sons whose mothers lived in a stable social environment. In addition, the courtship behavior of these sons is frequently integrated into play behavior. These effects can be regarded as behavioral infantilization, which corresponds with delayed development of the adrenocortical system (i.e., the typical decrease in concentrations of cortisol,

the main glucocorticoid in guinea pigs, with age is delayed) and – in contrast to daughters – decreased activity of the SAM system indicated by lower tyrosine hydroxylase activity. Finally, males whose mothers lived in an unstable social environment show a downregulation of AR expression in the MPOA and the ARC of the hypothalamus and of ER- α in the CA1 region of the hippocampus compared to males whose mothers lived in a stable social environment.

Comparison with Other Nonhuman Mammals

As these studies in guinea pigs show, prenatal factors can influence male and female offspring in different ways: the behavior of the female offspring is masculinized, whereas the behavior of the male offspring is infantilized. Interestingly, similar effects have been found in other studies investigating effects of prenatal social stress on offspring development, even though different stressors and different species were used. One common trait of prenatally stressed females can be described as a masculinization. In guinea pigs, this masculinization affects behavior, hormonal state, and sex steroid receptor distribution in specific parts of the limbic system. Aspects of masculinization also exist in mice and bank voles. A second characteristic feature of females prenatally exposed to social stress is a more-or-less severe impairment of reproductive function later in life. For example, in mice, less receptivity, delayed puberty, and altered estrus cycles are described. In male offspring, prenatal social stress frequently leads to a less pronounced expression of male-typical traits and/or a delay in development. In guinea pigs, this affects behavior, endocrine systems, and sex steroid receptor distribution in specific parts of the limbic system and is designated as infantilization. In other species (e.g., mice, rats and bank voles), similar effects are described in terms of demasculinization (i.e., the loss or attenuation of male-typical traits) and feminization (i.e., the expression of female-typical traits). Furthermore, some studies report an impairment in the function of reproductive organs, poorer motor abilities, altered emotional behavior, and effects on learning and memory.

In those few studies that consider offspring of both sexes, sex-specific or even sex-reversed effects are described. For example, in squirrel monkeys, prenatally stressed daughters show higher levels of immunoglobulin G (IgG), whereas in sons IgG concentrations decline. However, in most studies either the effects of prenatal social stress are investigated in only one sex or the sex is not identified.

Neuroendocrine Mechanisms of Prenatal Social Stress

A single neuroendocrine pathway clearly cannot explain the consequences of prenatal social stress. Rather, a variety of mechanisms is probably involved. For many aspects, prenatal social stress affects the offspring in a sex-specific and sex-reversed way. Furthermore, at least in guinea pigs, female offspring seem to be more susceptible to this stress than male offspring (see Table 1). However, a higher responsiveness to prenatal social stress in males has also been shown.

Pituitary Adrenocortical System

There is general agreement that maternal steroids play a decisive role in shaping fetal brain development. Most authors favor a role of the maternal hypothalamic pituitary adrenocortical (HPA) system in mediating the effects of the social environment during pregnancy on the offspring's behavior. Prenatal social stress often results in an activation of the maternal HPA system, and as a consequence the secretion of glucocorticoids is elevated. Thus, in male offspring mainly two different mechanisms are discussed: the high maternal glucocorticoid concentrations can influence the development of the fetus both directly and indirectly. In the male fetus a testosterone surge during a critical period of sexual differentiation is necessary for the masculinization of brain and behavior. It is known that high glucocorticoid concentrations can suppress testosterone secretion. Thus, the elevated glucocorticoid concentrations resulting from prenatal stress can eliminate or attenuate the testosterone surge in the male fetus. This can cause the behavioral demasculinization of the prenatally stressed males.

In female offspring a different mechanism is discussed. An activation of the HPA system triggers the secretion not only of glucocorticoids but also of androgens from the adrenal cortex. (The adrenal cortex consists of three different zones: the outermost zona glomerulosa [secreting mineralocorticoids like aldosterone], the middle zona fasciculata [secreting glucocorticoids], and the innermost zona reticularis [secreting androgens].) Since androgens are able to cross the placenta, they might cause a masculinization of the female embryonic hypothalamus during a critical period of sexual differentiation.

Sympathetic Adrenomedullary System

The preceding hypotheses assume that the pituitary adrenocortical system is involved during pregnancy in mediating the influence of the social environment on the development of the offspring, and numerous experiments support this view. However, there are

also indications that the HPA axis does not necessarily need to be involved. At least in some cases, an alternative pathway, which may include the maternal sympathetic adrenomedullary system, seems more likely, as can be seen from studies in guinea pigs. Surprisingly, pregnant females of this species living in stable and unstable social conditions do not differ in plasma concentrations of cortisol. Even the introduction into a group of unfamiliar conspecifics does not result in increased cortisol levels 2 h later. Thus, ongoing activity of the pituitary adrenocortical system in pregnant females living under stable and unstable social conditions is probably mostly comparable. In contrast to cortisol, serum dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) concentrations are lower in pregnant female guinea pigs living in an unstable social environment compared to controls. DHEA and its sulfate are, in addition to cortisol, the major hormones produced by the adrenal cortex. DHEAS *per se* has no effect, but it serves as a hormone pool for DHEA. Although DHEA is a weak androgen, it can exert both estrogenic and androgenic effects. This may be due to the fact that both DHEAS and DHEA are converted to testosterone and 17 β -estradiol in nonendocrine cells such as macrophages.

It has been reported that pregnant female guinea pigs living in an unstable social environment show a behavioral activation. This could be the reason for the reduced androgen concentrations of such females, because a behavioral activation usually is correlated with an increased activity of the SAM system. If so, the decreased DHEAS and DHEA concentrations probably result from the elevated level of catecholamine production in the adrenal medulla, since it is well known that catecholamines suppress DHEA(S) secretion. Due to low serum levels of maternal DHEAS, lower serum levels of estrogens or androgens might be expected in the fetus. If so, a significant impact on fetal brain development might occur.

A recent experiment supports the hypothesis that there is a relationship between the decreased androgen concentrations of pregnant females living in an unstable social environment and the behavioral infantilization of their male offspring. The decreased androgen concentration is experimentally mimicked by application of the antiandrogen flutamide during the sensitive phase of fetal CNS sexual differentiation. Sons of mothers who have received the antiandrogen during pregnancy show a similar behavioral infantilization later in life, as do sons whose mothers have lived in an unstable social environment during pregnancy.

The results regarding the masculinized daughters of females living in an unstable social environment are confusing. In mammals, masculinization occurs if sufficient androgens are available during a critical period of sexual differentiation. In the case of insufficient concentrations of androgens, a female pattern develops. In guinea pigs, however, pregnant females who have lived in an unstable social environment show decreased androgen concentrations, but the daughters are behaviorally masculinized. Thus, for guinea pigs it seems unlikely that elevated maternal androgens resulting from social stress during pregnancy bring about a behavioral masculinization of their daughters. Nevertheless, androgens do seem to be involved: masculinized daughters show male-typical patterns of androgen receptor expression in the MPOA and the ARC, two brain areas that are well known to play an essential role in the control of sex-typical behaviors and the regulation of gonadotropin-releasing factors. However, at present the neuroendocrine mechanism is not clear.

Adaptive Function of Prenatal Social Stress

The characteristic traits of individuals who were exposed to environmental stimuli (stressors) during pregnancy (e.g., masculinization of daughters, feminization of sons, heightened levels of anxiety, increased cortisol responses to stressors) are often regarded as deviation from the norm or even as pathological. Alternatively, and in accordance with current evolutionary theory, these traits might represent adaptive maternal effects as well. That is, mothers try to maximize their own Darwinian fitness by efficiently adjusting their offspring to the current environmental conditions.

Effects of Prenatal Social Stress in Guinea Pigs: Pathology or Adaptation?

If prenatal influences on behavior indeed are adaptive, the following questions arise: What is the benefit of being a masculinized daughter? What is the benefit for sons who show a less pronounced expression of male-typical traits and/or a delay in development? So far, there are no empirical data to answer these questions, but reasonable hypotheses in accordance with evolutionary theories on maternal effects can be derived.

Fluctuations of natural populations of small mammals with alternating states of high and low population density are a well-known phenomenon. They also have been documented in natural populations of the feral ancestor of the domestic guinea pig. In this species, population densities can change considerably, even from year to year. Under high-density conditions,

social instability is a common trait, whereas low population densities are characterized by stable social situations. Hence, pregnant female guinea pigs can experience completely different degrees of social stability not only under experimental laboratory conditions but also in their natural habitats.

If a pregnant female that lives in a high-density population has the possibility to preprogram her daughter so that she will fit optimally into a high-density situation, what should she do? A reasonable answer is to masculinize her female offspring in order to make them more robust and/or more competitive. These traits could help her daughter more efficiently defend important resources, such as food and shelter, which are scarce in high-density situations. However, a characteristic feature of females that are masculinized behaviorally due to prenatal stress is a more-or-less severe impairment of reproductive function later in life. Thus, under high-density conditions, there is a trade-off between the benefits of a behaviorally and endocrinologically masculinized phenotype and the costs of decreased reproductive success. Nevertheless, under such conditions, the chances of reproductive success would be expected to be greater in masculinized than in nonmasculinized females. Under low-density conditions, sufficient resources are available and fewer competitive abilities are needed, so it is more beneficial to invest time and energy into reproductive effort rather than to build and maintain a male-typical phenotype to defend resources. Thus, under low-density conditions, chances of reproductive success would be greater in nonmasculinized females compared to masculinized ones.

Similarly, if mothers program their male offspring prenatally such that a less pronounced expression of male-typical traits and/or a delay in development occur, they will provide them with a promising reproductive strategy under conditions of high density.

Prevalence of Traumatic Events and Sexual Assault

Psychological Sequelae of Sexual Assault

Treatment of Sexual Assault-Related PTSD

Predictors of PTSD

Conclusion

Glossary

Arousal

A cluster of PTSD symptoms that includes concentration problems, anger, exaggerated startle response, sleep disturbance, and being overly alert.

Avoidance

A cluster of PTSD symptoms including behavioral and psychic avoidance, such as avoidance of thoughts, feelings, and reminders of the trauma; emotional numbing; loss of interest in activities; feeling disconnected from others; psychogenic amnesia; and a sense of fore-shortened future.

Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)

A reference manual used by mental health professionals that includes descriptions and diagnostic criteria for psychiatric disorders.

Posttraumatic stress disorder (PTSD)

An anxiety disorder that develops in response to a traumatic event and is characterized by three clusters of symptoms re-experiencing, avoidance, and arousal. PTSD is diagnosed after a 1-month period of sustained symptoms following the traumatic event.

Prevalence

How widespread a disorder or an event (e.g., sexual assault) is at a given time.

Re-experiencing

A cluster of PTSD symptoms that includes experiencing the trauma in the form of nightmares, flashbacks, intrusive distressing thoughts, or becoming intensely emotionally upset or having physiological arousal upon exposure to reminders of the trauma.

Trauma

An event experienced or witnessed, in which an individual is subjected to the threat of death, injury, or physical integrity, and during which an individual feels terrified, horrified, or helpless.

Prevalence of Traumatic Events and Sexual Assault

Estimates of exposure to traumatic events vary, but on the whole, they are quite high. Several studies have examined rates of traumatic experiences in the general population. In a nationally representative sample of approximately 6000 people, ages 15–54, 60% of men and 51% of women reported experiencing at least one traumatic event in their lifetime. Similar findings emerged from a second study using a large, racially diverse sample; 74% of men and 65% of women reported experiencing at least one traumatic event. Somewhat lower prevalence was found in a sample of young adult health maintenance organization (HMO) members ($n = 1007$): 43% of men and

39% of women reported a traumatic experience in their lifetime. This discrepancy may be accounted for by differences in the samples; members of an HMO may be of higher socioeconomic status than the general population, which may have shielded them from a high-risk level of exposure to trauma. Studies examining rates of trauma exposure internationally have found similarly high levels of exposure. In a large sample of four cities in Mexico, 76% of the participants reported at least one traumatic event in their lifetime, and the majority of the participants experienced multiple versus single traumas.

Another large epidemiological study examined rate of exposure to traumatic events among a representative sample of 4000 women. Consistent with other results, almost 70% of women reported having experienced a traumatic event during their lifetime. In addition to these high rates of single trauma exposure, prevalence data have shown women to be at high risk for experiencing multiple episodes of violence throughout their lives.

Women are more likely than men to experience the traumas of rape and sexual assault. In the literature, rape is typically considered oral or vaginal penetration, while sexual assault is a more broad term that encompasses the use of pressure and coercion to force sexual contact. Lifetime prevalence estimates of rape and sexual assault among women vary widely across studies, ranging from 2 to almost 30%. Among adult women, several studies estimated prevalence of completed rape to be 20%. Others, however, have documented much lower rates, ranging from 2 to 14%.

In an epidemiological study of 4008 women, the prevalence of completed rape was 13%; other types of sexual assault were reported by 14% of the sample. Prevalence of childhood sexual abuse is similarly high. In a nationally representative sample of 2626 adults, almost one-third (27%) of the women reported a history of sexual abuse (e.g., being touched, grabbed, kissed, shown genitals) during childhood. Of these women who reported childhood sexual abuse, 49% (13% of the entire sample) reported actual or attempted intercourse. Among adolescents, one study found that 43% of the sample had experienced a traumatic event, of which rape accounted for 2% of the traumas. Further, female adolescents were significantly more likely to report a completed rape than males, which highlights young women's risk for sexual assault. International samples also report similar levels of sexual assault in women. Of the types of trauma reported by women in the Mexico study, nearly 15% reported some type of sexual assault (10.5% sexual molestation, 3.9% sexual assault). Since sexual

assault is less likely to be reported to the police than other crimes, it is safe to assume that the rates mentioned above are an underestimation of the actual prevalence of sexual assault.

Psychological Sequelae of Sexual Assault

Posttraumatic Stress Disorder (PTSD)

Sexual assault is associated with a variety of psychological difficulties. Among the most common are symptoms of posttraumatic stress, a set of psychological and physical symptoms that follow a traumatic experience. In some cases, these symptoms persist beyond the immediate aftermath of the trauma and develop into posttraumatic stress disorder (PTSD), an anxiety disorder that includes symptoms of arousal, avoidance, and re-experiencing, which lasts for more than 1 month and causes significant impairment in social or occupational functioning. This disorder affects from 1 to 12% of the general population and close to 25% of those exposed to a traumatic event. Women appear to be twice as likely to develop PTSD as men (10% of women vs. 5% of men).

Retrospective and prospective studies show female victims of sexual assault to be at particular risk for developing PTSD. For example, Norris examined the impact of 10 common traumatic events (e.g., robbery, assault, disaster) in a large, racially diverse sample. Of all the traumatic events surveyed, sexual assault yielded the highest rate of PTSD (14% lifetime). Similarly, Resnick et al. found that 12% of rape victims had current PTSD compared to 3% of victims of nonviolent traumas. Using a national sample of 1500 women, rape and sexual assault led to the highest lifetime (39%) and current (13%) rates of PTSD. In a community sample of 400 adult females, of women who had experienced a completed rape, 57% met lifetime diagnostic criteria and 17% met criteria for current PTSD. Lower rates (37% lifetime and 11% current) were found in females who had experienced a nonsexual assault.

Two prospective assessment studies have examined the prevalence of PTSD following sexual or nonsexual assault. In a study of female rape victims, 94% of the women met symptom criteria for PTSD within 2 weeks following the assault. Three months after the sexual assault, rates of PTSD had declined considerably; however, 47% continued to meet PTSD criteria. Women who did not meet criteria for PTSD 3 months after the assault showed a steady reduction in symptoms over the 12 weeks of assessment. Minimal symptom improvement was seen for those women

who continued to meet PTSD criteria 3 months after the trauma. Follow-up assessments conducted 6 and 9 months after the assault revealed that 42% of women continued to meet criteria for PTSD at each time point. In a second study, Riggs et al. found that 90% of rape victims and 62% of nonsexual assault victims met symptom criteria for PTSD within 2 weeks of an assault. At the 1-month assessment, the rate was 60% for rape and 44% for nonsexual assault survivors. At 3 months, the rate had dropped to 51 and 21% for rape and nonsexual assault survivors, respectively. Similar findings have been shown in adolescents, with those who experienced a sexual assault being seven times more likely to meet PTSD criteria compared to all other reported trauma types. These results, taken together, suggest that sexual assault is more likely to produce PTSD than other simple assaults.

Prevalence of other Psychological Reactions

Reactions to sexual assault other than PTSD are also common. Anxiety, anger, depression, substance abuse, and dissociation occur with high frequency and are discussed in the following sections.

Anxiety Anxiety and fear are among the most common reactions to sexual assault, but are often discussed under the rubric of PTSD. After an assault, women are often quite afraid of rape- and assault-related situations and also experience general anxiety at high levels. Such fears have been documented to last up to 16 years postassault. Indeed, in one study, only 23% of sexual assault victims did not show elevated fear 1 year after the assault. Although victims' fearfulness declined over time, they remained more fearful than nonvictimized controls 1 year after the assault. Thus, fear and anxiety levels remain elevated in many victims of sexual violence long after the assault.

Anger

Elevated anger levels are often seen among sexually assaulted women compared to nonvictimized controls. In a prospective study of 116 rape and other crime victims and 50 matched nonvictimized controls, Riggs et al. found that level of anger was related to aspects of the assault such as the use of a weapon and the victim's response to the attack. In addition, elevated anger levels were related to PTSD symptoms 1 month after the assault. Similarly, Feeny et al. found anger levels 1 month after an assault to be predictive of PTSD symptom severity at 3 months postassault. The authors hypothesized that anger interferes with

recovery by preventing emotional processing of the traumatic event.

Depression Depression is another common reaction to sexual assault, although some evidence suggests that it is less persistent than fear and anxiety. In a study of psychological reactions to rape, Frank and Stewart found that almost half of their sample was diagnosed with major depression; however, over 3 months' time, these symptoms declined considerably. Retrospective examinations of depression among trauma victims, however, suggest more enduring symptoms. For example, one study found that an average of almost 22 years postassault, rape victims were more depressed than nonvictims.

In the North Carolina catchment area study, the lifetime prevalence rate of depression was significantly related to sexual assault: women who had been sexually assaulted were more than twice as likely to manifest a major depressive episode as women who had not been sexually assaulted. In addition, comorbidity of PTSD and depression is high: 48% of those who met lifetime criteria for PTSD also met lifetime criteria for depression, and 43% evidenced current comorbidity of the two disorders. In a sample seeking treatment for PTSD, 63% met criteria for current major depression. These results suggest that depression should be routinely assessed in victims of trauma who are seeking treatment.

Substance abuse Female assault victims, particularly those who develop PTSD, are also at risk for substance abuse. In a national probability sample of women, crime victims (sexual and nonsexual assault) were at increased risk of developing an alcohol use disorder, independent of their PTSD status. Moreover, those diagnosed with PTSD were 3 times more likely to have serious alcohol problems than those without the disorder and 14 times more likely than those without a history of criminal victimization. In the North Carolina catchment area study, lifetime prevalence of substance (alcohol and drugs) abuse and dependence was significantly related to the presence of sexual assault. In a recent longitudinal study, recent and past assault were associated with two to three times the risk of alcohol abuse in women, even after controlling for past alcohol use, age, race, and education.

Additionally, the prevalence of PTSD in patients enrolled in a substance abuse treatment program ranges from 12 to 34%, and prevalence rates are significantly higher among women, ranging from 33 to 59%. Among psychiatric outpatients, the rate of victimization among alcoholic women was higher

than among nonalcoholic women, suggesting a specific link between early victimization and later alcohol abuse among adult women. In summary, being a victim of a trauma appears to substantially increase the risk of developing a substance use disorder and vice versa: substance abuse seems to increase the likelihood of victimization.

Dissociation The construct of dissociation typically focuses on three clinical entities: alterations in memory (e.g., aspects of the trauma not consciously accessible), in identity (e.g., disengagement between self and environment), and in consciousness. Dissociation has been conceptualized to reflect emotional disengagement from trauma memories, which has been thought to hinder recovery. Indeed, several studies suggest that dissociation does hinder the processing of the traumatic event and subsequent natural recovery process. Trauma victims with PTSD exhibit more dissociative symptoms than those without PTSD. Moreover, if dissociation is present during or immediately after a trauma it is predictive of later psychopathology. Similarly, acute stress disorder, which emphasizes dissociative symptoms, has been found to be predictive of later posttrauma symptoms. The role of dissociation in promoting emotional disengagement needs further exploration in studies that evaluate risk factors in trauma exposed individuals.

Treatment of Sexual Assault-Related PTSD

Several cognitive behavioral treatment (CBT) programs have been developed to treat PTSD related to sexual assault, including exposure therapy, stress inoculation training (SIT), cognitive therapy (CT), eye movement desensitization and reprocessing (EMDR), and cognitive processing therapy (CPT). In this section, outcome studies, which evaluate the efficacy of these treatments with assault victims, are reviewed.

Recent studies examining the use of CBT with female sexual and physical assault victims have utilized well-controlled designs, and all but one utilized many of the methodological gold standards proposed by Foa and Meadows, including presence of PTSD diagnosis, assessment of PTSD severity, reliable and valid measures of related psychopathology, randomization to treatment conditions, and presence of control or comparison groups.

Prolonged exposure (PE) is an exposure therapy program that involves confrontation aimed at ameliorating PTSD, which typically includes mentally reliving the traumatic event repeatedly and *in vivo*

confrontation with trauma-related situations, which evoke fear but are not objectively dangerous. In the first controlled study of exposure for rape-related PTSD, the efficacy of PE, SIT, supportive counseling (SC), and a wait-list control was compared for female victims of sexual assault. PTSD symptoms were assessed at pretreatment, posttreatment, and follow-up evaluations with psychometrically sound interviews and self-report measures administered by trained clinicians who were blind to treatment assignment. PE and SIT showed significant pre-post reductions on re-experiencing and avoidance clusters of PTSD, while SC and wait list did not. Also, at the end of treatment 50% of patients in SIT and 40% of those in PE no longer met criteria for PTSD; in contrast, only 10% of SC patients and none in the wait list no longer met diagnostic criteria. At follow-up, patients in the PE group tended to show further reduction in PTSD symptoms, whereas patients in SIT and SC did not show further improvement.

In a second study, Foa et al. obtained further support for the efficacy of a modified PE in treating rape-related PTSD. This study compared the efficacy of PE to SIT, a combination of both treatments (PE/SIT), and a wait-list condition. All active treatments resulted in substantial symptom reduction and were superior to the wait-list condition in ameliorating PTSD and related symptoms. PE was superior to the other treatments: it effected a greater reduction of anxiety and depression and resulted in fewer drop-outs than SIT and PE/SIT. In addition, the number of patients who achieved good end-state functioning tended to be larger for the PE group than for the SIT and PE/SIT groups. In a third study, Foa et al. examined the efficacy of PE relative to a program that includes PE and cognitive restructuring (PE/CR). Results indicated that PE and PE/CR were superior to wait list at posttreatment on measures of PTSD and depression, with these gains maintained at follow-up. The addition of the cognitive restructuring component did not appear to enhance treatment outcomes; as with most posttreatment outcomes, PE and PE/CR did not differ from one another. Additionally, no differences in outcome were found among patients who were treated by experienced or recently trained counselors, suggesting that PE could be easily disseminated into community settings.

EMDR is a form of exposure accompanied by saccadic eye movements that has been the focus of considerable controversy due to initial claims of remarkable success in only a single session. Of the number of studies evaluating the efficacy of EMDR, only a few utilized well-controlled designs and thus yielded interpretable results. One well-controlled

study evaluated the efficacy of EMDR relative to a wait-list control condition for PTSD in female rape victims. Three sessions of EMDR resulted in greater improvement for PTSD symptoms (57% reduction in independently evaluated PTSD at posttreatment and 71% in self-reported PTSD at follow-up), relative to the wait-list condition (10% reduction at posttreatment). However, in contrast to other controlled studies, one therapist conducted all treatments, and therefore the contribution of therapist and treatment effects were confounded. A more recent study comparing PE and EMDR found that both treatment groups had significant reductions in PTSD symptoms at posttreatment. At 6-month follow-up, PE resulted in more adaptive scores on a number of anxiety and depression measures than those seen for participants who received EMDR. This study provides further support for the use of exposure techniques in the treatment of sexual assault.

Another recent study compared EMDR, PE, and relaxation training. This study found that PE effected the largest reductions in symptoms of re-experiencing and avoidance compared to EMDR and relaxation training and also effected the quickest reduction in avoidance symptoms. This study reported that EMDR and relaxation training did not differ from each other in efficacy or speed of change. Additionally, recent meta-analyses have found no evidence that the use of eye movements, integral to this treatment, have any effect on treatment outcomes. Thus, the use of the exposure techniques, which are a part of this treatment protocol, appears to account for the treatment outcomes using EMDR.

CPT is a program that was developed specifically for use with rape victims and includes cognitive restructuring and an exposure variant (i.e., writing the traumatic memories and reading the account aloud to the therapist). In a quasi-experimental design, CPT was compared to a naturally occurring wait-list control group. Overall, women who received CPT improved significantly from pre- to posttreatment (about 50% reduction in PTSD symptoms), whereas the wait-list group did not show significant improvement. In a second study, Resnick et al. compared the efficacy of a 12-session CPT, a 9-session PE, and a wait-list control in rape victims with chronic PTSD. After 9 weeks of PE and 12 of CPT, both treatments were highly effective in reducing PTSD symptoms. At follow-up assessments 3 and 9 months posttreatment, treatment gains were maintained.

A treatment specifically designed for women who experienced childhood sexual abuse has also been investigated; it is similar to CPT in that it is a combination treatment utilizing exposure and cognitive

components. This treatment consists of skills training in affect and interpersonal regulation followed by a modified PE protocol (STAIR-modified PE). In a controlled study, relative to a wait-list condition, participants receiving STAIR-modified PE showed significant improvement in symptoms of PTSD, as well as improvements in affect regulation. This study provided evidence for the use of CBT procedures with childhood abuse survivors; however, future studies should compare the usefulness of the addition of the skills training as compared to PE alone, as previous studies utilizing PE have not found beneficial effects of adding components beyond exposure techniques.

In summary, the CBT program that has received the most empirical support in controlled studies is PE, and its efficacy in reducing PTSD symptoms is at least as high as that of comparison CBT programs. Additionally, recent evidence suggests that it can be successfully used in community settings. Thus, at present, PE is the recommended psychosocial treatment choice.

Predictors of PTSD

As is apparent from the results reviewed previously, not all women who have been sexually assaulted develop chronic PTSD; thus the identification of factors that are involved in hindering recovery has been the focus of much investigation. Foa and Riggs proposed to classify predictors into three categories: pretrauma, trauma, and posttrauma variables. In terms of pretrauma variables, it appears that poor psychological functioning prior to the trauma renders the individual vulnerable to developing chronic disturbances posttrauma. In addition, a prior history of traumatic events in child- or adulthood intensifies the response to subsequent trauma. Factors related to the trauma itself, including trauma severity, also appear to predict the development of PTSD, as well as posttrauma variables such as social support.

In a prospective study of 277 female assault victims, Amir et al. tested a predictive model of PTSD that included all three domains thought to be relevant to the prediction of PTSD. Several variables emerged as significant predictors at 1 and 3 months post-assault: trauma history, trauma severity, cognitions and complex emotions, basic emotions, and early PTSD symptoms. Trauma history had an impact on cognitions and emotions, which, in turn, influenced PTSD symptom severity 4 and 12 weeks after the assault. Trauma severity influenced PTSD symptoms 2 weeks after the assault.

Recent meta-analyses provide additional information regarding the predictors of PTSD. One

meta-analysis found that the effects of predictors varied based on the sample under investigation; however, three variables were consistently significant predictors of PTSD: psychiatric history, childhood abuse, and family psychiatric history. Also, the largest effect sizes were found with predictors that were at or around the time of the trauma (e.g., social support following trauma). A second meta-analysis reviewed 476 studies that investigated PTSD predictors. Of the reviewed studies, 68 evaluated several of the hypothesized major predictors of PTSD, which include prior trauma, prior psychological adjustment, family history of psychopathology, perceived life threat, posttrauma social support, emotional response to trauma, and dissociation to trauma. Of these predictors, dissociation at the time of the trauma was the largest predictor of later developing PTSD. Indeed, the predictors with the largest effect sizes were those that were related more proximally to the trauma itself (e.g., dissociation and emotional response), similar to the finding in the Brewin et al. analyses. These results underscore the complexity of the mechanisms underlying the development of PTSD.

Conclusion

The majority of people in the United States are exposed to at least one traumatic experience in their lifetime; however, only a minority develop long-lasting psychological difficulties, including chronic PTSD. Importantly, not all traumas are equal in causing the development of PTSD; traumas inflicted by another person, especially sexual assaults, are particularly prone to produce lasting disturbances.

Once established, PTSD is unlikely to remit unless treated. The most empirically validated type of therapy for this disorder is CBT, and among the various CBT programs, PE has gained the most empirical support.

Summary

Glossary

<i>Anxiety</i>	A symptom of stress.
<i>Spectatoring</i>	Monitoring one's sexual arousal, looking for signs of failure.
<i>Stress</i>	A subjective, phenomenological experience that is thought of by the individual experiencing it to be aversive; stress is generally thought to be a response to some external event or situation.
<i>Stressor</i>	External condition or situation that can cause a stress response in a given individual.

The *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV-TR) characterizes sexual dysfunctions as either disturbances that occur in one of the four phases of the sexual response cycle or by pain that is associated with sexual intercourse. The four phases of the sexual response cycle are desire, excitement, orgasm, and resolution. The desire phase consists of fantasies about and the motivation to engage in sexual activity. The excitement stage includes a subjective sense of sexual pleasure and corresponding physiological changes, with major changes in males being tumescence and erection, and in females vasocongestion in the pelvis, vaginal lubrication and expansion, and the swelling of the external genitalia. The orgasm phase consists of a peaking of sexual pleasure accompanied by the release of sexual tension and contraction of the perineal muscles and reproductive organs. In males, ejaculation of semen occurs in this phase, and in females, there are rhythmic contractions of the wall of the vagina. Finally, the resolution phase involves a sense of muscular relaxation and well-being. Males are physiologically refractory to another erection and orgasm for a period of time; however females can respond to additional stimulation almost immediately.

Sexual dysfunction can occur in any one of these phases or more than one, and factors such as age, experience, frequency and chronicity of the symptoms, subjective distress, and the symptoms' effects on other areas of functioning must be considered. The sexual dysfunction disorders as outlined in the DSM-IV-TR include sexual desire disorders (hypoactive sexual desire disorder and sexual aversion disorder), sexual arousal disorders (female sexual arousal disorder and male erectile disorder), orgasmic disorders (female orgasmic disorder, male orgasmic disorder, and premature ejaculation), sexual pain disorders (dyspareunia and vaginismus), sexual dysfunction due to a general medical condition, substance-induced sexual dysfunction, and sexual dysfunction not otherwise specified.

The prevalence of sexual dysfunctions is difficult to accurately report because, given the sensitivity of the issue, it is estimated that most cases go untreated or unreported. Of the epidemiological studies that have been conducted, there has been a large variability in terms of the prevalence of various sexual dysfunctions found in different populations. Other factors that might be contributing to these different findings could be the use of different assessment methods, the definitions used, or simply the varying characteristics of the samples used. Studies have estimated that the lifetime incidence of sexual problems is anywhere between 10 and 52% in males and 25 and 63% in females, whereas other studies have found ranges of only 5–13% in males and females.

Etiology

Research has demonstrated that the onset of sexual dysfunction varies greatly in that it could be present from the initial onset of sexual functioning or it could occur after a period of normal sexual functioning. Sometimes sexual dysfunction is not limited to certain types of stimulation, situations, or partners, and sometimes it is. Several considerations must be taken into account when making clinical judgments about the presence of a sexual dysfunction. Among these considerations are the individual's ethnic, cultural, religious, and social backgrounds. Another factor that adds a considerable degree of subjectivity to the diagnosis is the adequacy of sexual stimulation. There are no norms for this or for any of the factors clinicians must render judgments about. These factors may all influence individuals' sexual desire, expectations around sexual activity, and attitudes about their and their partner's performance.

There are also several risk factors associated with sexual dysfunctions that might be biological or psychological in nature. Biological factors can either directly lead to sexual problems or indirectly contribute. Some of the most common direct biological risk factors for sexual dysfunction include vascular disease, diabetes, hormone levels, the use of alcohol, and the use of certain medications (for example antihypertensives). Common indirect biological risk factors include age, cigarette smoking, chronic pain, heart disease, cancer, and other medical procedures that might alter an individual's appearance, leading to body-image insecurities and possible subsequent problems with normal sexual functioning. Psychological risk factors for sexual dysfunction include the presence of mood disorders, anxiety disorders, substance use disorders, eating disorders, and, largely, stress. Various negative life stressors adversely affect sexual functioning, including job stress, financial stress, bereavement or the loss of a loved one, divorce or relationship problems, problems conceiving, and marriage. Much of the literature examining the risk factors associated with sexual dysfunction in humans is correlational; however, studies using animals have provided more substantial evidence about the effects of stress on sexual functioning. Specifically, researchers have found that both physical stress (e.g., shock or immobilization) and social stress (e.g., overcrowding, other aggressive animals attacking, or isolation) result in copulatory disorder (equivalent to male erectile disorder in humans) in male mice and that, when faced with more mild stressors, mice copulatory behavior decreased. These findings are consistent in research conducted with human sexual behavior when faced with life stressors. Sexual dysfunction has been found to be more prominent among couples who report more severe and greater stressors in their lives compared to couples who report having fewer life stressors. In addition, sexual desire has been found to be lower or absent in individuals who report higher levels of occupational stress. Finally, research has discovered that sexual dysfunction is more likely in couples in which one or both partners have a diagnosed anxiety disorder.

Anxiety and stress, although appearing to frequently have different operational definitions, are frequently used interchangeably in the literature. Some studies examining the effects of anxiety on sexual arousal have produced the interesting findings that anxiety was found to negatively affect sexual arousal in individuals with sexual dysfunction but may actually enhance arousal in individuals with normal sexual functioning. It is possible that when sexually functional men and women become anxious during sexual activity, their autonomic arousal increases and they focus more on erotic cues, which enhances their

arousal. Individuals with sexual dysfunction, on the other hand, become anxious, and when their autonomic arousal increases, they focus on not being able to perform (which Masters and Johnson called "performance anxiety" or spectating) and subsequently fail to become aroused.

When a sexual dysfunction is present, it often acts as an additional source of stress in the individual's or couple's lives, serving only to further exacerbate the dysfunction. This appears to be especially true in couples who are trying to conceive because there is not only pressure to perform sexually for pleasure and intimacy but also to get pregnant. Arguments, blame, embarrassment, and a lack of communication about sexual dysfunction can also increase stress and cause the sexual problem to remain unimproved.

Sexual Desire Disorders

The sexual desire disorders include hypoactive sexual desire disorder and sexual aversion disorder. Hypoactive sexual desire disorder is characterized by a deficiency or absence of sexual fantasies and desire for sexual activity, taking into consideration age and the individual's personal history. Sexual aversion disorder is characterized by a persistent or recurrent extreme aversion to and avoidance of all, or almost all, genital sexual contact with a sexual partner. Possible stress-related causes of both of the described disorders include anxiety over difficulty getting aroused or climaxing, marital stress, fear of intimacy, fear of losing control, guilt or religious prohibitions, fear of sexually transmitted diseases, fear of blood or pain during intercourse, posttraumatic stress disorder following rape or sexual assault, or a secondary trigger for panic disorder. Women are twice as likely to experience the desire disorders and are also more likely to report higher levels of psychological distress than men, more marital dissatisfaction than men, and greater self-reported stress levels than men, specifically in the areas of related to home and finances. Most frequently, hypoactive sexual desire disorder develops in adulthood, after a period of normal sexual functioning, in association with stressful life events or interpersonal difficulties.

Sexual Arousal Disorders

The sexual arousal disorders consist of female sexual arousal disorder and male erectile disorder. Female sexual arousal disorder is characterized by a persistent or recurrent inability to attain, or maintain until completion of the sexual activity, an adequate lubrication and swelling response of sexual excitement. Male erectile disorder is characterized by a persistent or recurrent inability to attain, or to maintain until

the completion of the sexual activity, an adequate erection. Women who experience female sexual arousal disorder often report little or no subjective sense of arousal and are unlikely to seek professional treatment because this problem can frequently be remedied with the aid of a lubricant. Without intervention, female sexual arousal disorder can result in painful intercourse, avoidance of sexual activity, and relationship problems. With male erectile disorder, different patterns can be seen with this sexual dysfunction. Some individuals may have difficulty obtaining an erection, some are able to obtain an erection but lose it when attempting penetration, some are able to sustain an erection on penetration but cannot on thrusting, and other males are able to sustain an erection only during self-masturbation or on awakening. Erectile difficulties are frequently associated with sexual anxiety, fear of failure, anxiety over sexual performance, and a decreased subjective sense of sexual excitement and pleasure. Erectile dysfunction can cause marital and relationship problems and may be the cause of infertility. The introduction of Viagra has caused male erectile disorder to become well known and in some cases obsolete.

Orgasmic Disorders

The orgasmic disorders consist of female orgasmic disorder, male orgasmic disorder, and premature ejaculation. Female orgasmic disorder is characterized by a persistent or recurrent delay in, or absence of, orgasm following a phase of normal female arousal taking into consideration the woman's age, sexual experience, and adequacy of sexual stimulation that she receives. Male orgasmic disorder is characterized by a persistent or recurrent delay in, or absence of, orgasm following a phase of normal male sexual arousal taking into consideration the man's age and his adequacy in focus, intensity, and duration. Premature ejaculation is characterized by a persistent or recurrent ejaculation with minimal stimulation before, on, or after penetration and before the individual wishes it. Stress-related etiological factors for women with female orgasmic disorder can include marital dissatisfaction, high levels of distress, and interpersonal stress. In addition, female orgasmic disorder has been found to adversely affect women's body image and self-esteem, which can then exacerbate the sexual dysfunction. Male orgasmic disorder is associated with performance anxiety, spectatoring, previous sexual traumas, and sexual and marital dissatisfaction. Premature ejaculation is associated with embarrassment and reluctance to engage in a sexual relationship due to fear of rejection and ridicule. Males with premature ejaculation often socially isolate themselves to prevent these events from taking place.

Sexual Pain Disorders

Sexual pain disorders include dyspareunia and vaginismus. Dyspareunia is characterized by recurrent or persistent genital pain associated with sexual intercourse in either a male or a female. Vaginismus is characterized by recurrent or persistent involuntary contraction of the perineal muscles surrounding the outer third of the vagina when penetration with a penis, finger, tampon or speculum into the vagina is attempted. Stress-related etiological factors associated with dyspareunia include anxiety, guilt from religious inhibitions, poor body image, and marital or relationship dissatisfaction. Vaginismus is associated with anxiety, interpersonal stress, and prior sexual abuse or traumatization.

Interventions

If stress is found to be an underlying cause of the sexual dysfunction, treatment will include strategies designed to decrease stress.

Psychoeducation

Psychoeducation can be a powerful tool in alleviating sexual dysfunction, not only in its ability to inform individuals but also to address false beliefs, unrealistic expectations, and lack of knowledge about physiology, anatomy, and normal sexual functioning, and it can, in and of itself, relieve anxiety associated with doing it wrong or feeling abnormal. As a result, psychoeducation can lead to rapid improvements in only a couple of sessions. Excerpts from human sexuality textbooks, complete with diagrams and pictures, can help provide a comprehensive overview of sexual functioning. Addressing common myths associated with human sexual functioning can also be helpful in educating individuals with sexual dysfunction.

Systematic Desensitization

Systematic desensitization is an effective therapy strategy designed to reduce anxiety. The individual is first equipped with relaxation skills and then is asked to come up with a hierarchy of increasingly anxiety-provoking stimuli or situations. When using this technique, an individual is placed in a deeply relaxed state and is presented with a series of gradually increasing anxiety-provoking situations using imaginal exposure. The therapist starts with the least anxiety-provoking stimulus on the hierarchy and then slowly works up to more anxiety-inducing stimuli. The therapist asks the individual to imagine the stimulus, and when the individual experiences anxiety during the exposure exercise, the therapist asks the individual to allow him- or herself to get rid of the

image and then induces the original relaxed state. This procedure is used for longer and longer periods of time until the individual is able to retain the image without experiencing any anxiety; this is continued until the hierarchy is completed successfully.

Cognitive Restructuring

Intrusive negative thoughts can largely contribute to sexual dysfunctions. Ultimately, these thoughts interfere with sexual arousal and enjoyment because individuals are no longer able to concentrate on the sexual activity. Frequently, these negative thoughts may revolve around anxiety over their performance, one partner's dissatisfaction, or negative expectations about the sexual activity itself. In addition, individuals with multiple life stressors may experience thoughts concerning these stressors that may be a part of their sexual dysfunction and that can similarly disrupt sexual performance. In using cognitive restructuring, the therapist helps the individual identify these thoughts and then come up with other, more sensual or erotic thoughts to replace with these during intercourse. In this way, the individual can learn to turn the previously anxiety-provoking situation into a pleasurable one. In some cases, individuals have a difficult time coming up with the negative thoughts they typically have during intercourse. In these situations, it is useful to have them keep a diary, monitoring these thoughts as they occur and recording them following sexual activity. Another way to challenge individuals' negative thoughts is to help them determine whether the thoughts have any factual basis. This helps individuals let go of some negative and false assumptions that they might be carrying that are preventing them from enjoying intercourse.

Sensate Focus

Sensate focus is an effective tool used to help individuals with sexual dysfunction, specifically in cases in which performance anxiety appears to play a key role. Simply focusing on maintaining an erection or achieving an orgasm as the main goal of sexual intercourse can often cause anxiety to increase, particularly if there is a past history of the individual being unable to do so. Feelings of failure and disappointment can lead to increased anxiety about the next sexual encounter, and more preoccupation with achieving success often leads to subsequent failures. Sensate focus seeks to reduce anxiety by allowing individuals to take this pressure to perform out of the way by simply not allowing sexual intercourse for a time. A series of exercises are completed by the couple that include nonsexual touching and caressing while clothed, progressively moving through a series of increasingly demanding sexual activities over the

course of treatment. The individuals are taught to focus on the sensations they experience rather than engaging in spectating. Because the pressure to aspire to the ultimate goal of maintaining an erection or achieving an orgasm is no longer the focus, the couple is able to restructure its goals in sexual encounters and thus reduce the anxiety and stress associated with performance anxiety.

Couples Therapy

Interpersonal, marital, and couples issues appear to play a central role in the development and/or maintenance of several sexual dysfunctions. Many of these issues are significantly improved by the implementation of communication skills training. Most sexual partners have a difficult time discussing their sexual relationship with one another. There are often fears about hurting one another's feelings, saying the wrong thing, or not being able to feel that they can ask for more of what they want and less of what they do not want. An improvement in overall communication can increase relationship satisfaction while creating a more effective line of communication to discuss more delicate matters, such as the couple's sexual relationship. Conflict resolution skills are important in maintaining a fair and even balance in times when there might otherwise be power struggles, and these can also help to build trust and respect. Enhanced communication not only alleviates stress from the relationship but also can assist in bringing the couple closer, both of which can contribute to a more satisfying sexual relationship.

Pharmacological Interventions

As mentioned previously, Viagra has become a household name, and it and its competitor medications are making a huge impact on sexual dysfunction. Not only does it significantly alleviate erectile dysfunction in a large proportion of men (the female equivalent to Viagra is beginning to be developed and has seen promising results in alleviating female arousal disorder), but it is also helping to decrease the social stigma surrounding sexual dysfunction and is allowing individuals to feel more comfortable about disclosing this problem to their physicians. The negative side to this is that, because it has become so convenient to get a prescription for this type of sexual enhancement drug, it is beginning to be abused by individuals who do not have sexual dysfunction and are simply using it recreationally. Naturally, physicians do not want to make it difficult for individuals who honestly may be suffering from erectile dysfunction to receive available support and help, so they do not withhold prescriptions from individuals reporting that they need the

drug. Thus, for now, no effective solution has been proposed to prevent this abuse from taking place.

Summary

Sexual dysfunctions are very common, affecting a large percentage of the population. Although epidemiological data are inconclusive, it is possible that only a small proportion of individuals suffering from sexual dysfunctions are being effectively treated. Stress appears to play a large role in the development, persistence, exacerbation, and maintenance of sexual dysfunctions. Several evidence-based interventions have been found to be effective with this population, including systematic desensitization, couples therapy, and sensate focus. In addition, pharmacological interventions have been helpful in alleviating the symptoms of sexual dysfunction. Further research is needed to continue to examine the role of stress in sexual dysfunctions and to development effective treatments to help prevent them.

Glossary

Ephebophilia

A paraphilia in which the object of sexual attraction is a pubescent youth (child or adolescent), but not yet a fully sexually mature person, of either sex; also called hebephilia.

Paraphilia

Recurrent, intense sexual urges and fantasies, sometimes accompanied by sexually driven behaviors, occurring over a period of at least 6 months, involving one or more of the following: (1) a nonconsenting partner (e.g., children or a rape victim), (2) an object or body part (e.g., fur or feet), or (3) a sensory/emotional state (e.g., pain or humiliation) not typically associated with the archetypal sexual-response cycle. Paraphilias may be obligatory, in which case they are necessary components for completing the sexual-response cycle, or nonobligatory, in which case they may sometimes be incorporated in the sexual-response cycle but are not always essential for its completion. Paraphilias may be either pathological or non-pathological depending on the degree to which they impair the paraphile's social functioning and emotional well-being. They may be dangerous (such as lust

	murder or autoasphyxiophilia) or benign (such as transvestic fetishism or foot partialism) depending on their potential for lethality or adverse physical or social impact on self or others.
<i>Pedophilia</i>	A paraphilia involving sexual arousal to a prepubescent child or children of either sex.
<i>Perversion</i>	Once a psychiatric term roughly equivalent in meaning to paraphilia; now generally a pejorative term used by non-professionals to describe “kinky” sex or other expressions of sexuality (e.g., homosexual behavior) of which they disapprove.
<i>Phenomenology</i>	In the study of paraphilias or other psychiatric phenomena, the scientific method in which the phenomena experienced by the individual, as measured by observation and/or self-report, are described and classified rather than explained or interpreted.
<i>Sex offender</i>	A legal term denoting an individual who has broken a law governing the conduct of sexual behavior; the term is usually reserved for individuals who have been convicted of a crime involving sexual behavior.
<i>Sexual-response cycle</i>	The sequence of stages and events typically occurring in the progression of sexual activity from the beginning of sexual arousal to orgasm and resolution. Based on work by Masters and Johnson and amplified by other sexologists, the sexual-response cycle is sometimes arbitrarily divided into five stages or phases: (1) desire phase (sometimes called libido or drive); (2) excitement phase (sometimes called arousal), in which sexual arousal normally builds; (3) plateau (the point of highest arousal sustainable short of triggering orgasm); (4) orgasm (or climax); and (5) resolution (sometimes called the refractory period), in which arousal returns to prebaseline desire and during which an additional stimulus does not immediately lead to a repetition of the cycle.

General Considerations

It is universally assumed to be axiomatic that victims of sexual assault in its various manifestations suffer from the stress of their experiences to one degree or another. However, little or no scientific investigation has been conducted that sheds light on the relationship of stress to the experience of having been sexually victimized. Among important unstudied and,

therefore, unanswerable questions are: What experiences are most likely to cause toxic stress, who is at greatest risk for developing stress-induced sequelae, and what factors might protect against or mitigate the adverse consequences of stress resulting from sexual victimization? It may be concluded, however, that those who work with and care for the sexually victimized are highly sensitized to the importance of stress-related components of sexual assault, whether the assault takes the form of uninvited genital exposure or rape with the threat of death.

The situation with respect to sex offenders is roughly equivalent, although there is the added variable that cultures typically do not concern themselves much with the impact of stress on sex offenders, who are generally regarded as willful evildoers and not as psychiatrically ill. In this article, it is not our intent to explore to any great degree the ongoing controversy of whether sex offenders are criminals or patients and the degree to which the psychiatric impairment in some sex offenders may influence culpability for their offending behavior.

The question of whether individuals who engage in illegal paraphilia-driven behaviors should be considered as having diminished criminal culpability given their psychiatric diagnosis is controversial and complex. Over a century ago, the eminent British psychiatrist Henry Maudsley expressed concern that society often fails to even consider such a possibility. He wrote, “If the law cannot adjust the measure of punishment to the actual degree of responsibility . . . that is no reason why we should shut our eyes to the facts; it is still our duty to place them on the record, in the confident assurance that a time will come when men will be more able to deal more wisely with them.”

By definition, however, sex offenders are criminals with offenses ranging from misdemeanors to felonies. The term sex offender is strictly a legal term. There is no psychiatric diagnosis of sex offender, although there is some overlap between psychiatry and the law in that some individuals who have diagnosable psychiatric illness do commit sex offenses. Some sex offenders, including but not limited to those with paraphilias, may be more likely than others to commit sex offenses as a result of their psychiatric syndromes. Although severe comorbid psychiatric conditions may mitigate social response (e.g., the punishment may be less severe for an exhibitionist responding to command hallucinations), sex offenders are generally assumed to have adequate volitional control over their offending behaviors and are, thus, expected to conform their behavior to the expectations of society. Those who do not are likely to feel the full measure of retribution social systems are capable of bringing to

bear in dealing with them. That response, inevitably, induces toxic stress.

Indeed, with the diminishing emphasis on rehabilitation and the ascendancy of retribution in American penology, punishment is meted out with the specific intention of subjecting sex offenders to pain, suffering, and the attendant stress the retributive penal philosophy guarantees. The response of society to sex offenses is deliberately and systematically to induce intensive stress in the offender by prescribing a continuum of ever harsher punishment ranging, at minimum, from humiliation and social opprobrium to often-lengthy prison sentences and, occasionally, death. These stressors are intentionally inflicted with full knowledge of the adverse consequences of the stress they engender.

The underlying philosophy of retributive penology appears to be threefold. First, it is axiomatic that in serious offenses, retribution by the state is both appropriate and desirable because the state itself and the social values it defends are directly aggrieved by the crime. Second, it is axiomatic that the state has the duty to punish on behalf of individuals more specifically aggrieved by the crime, to bring miscreants to justice as their proxy, which prevents the degeneration of retribution into vengeance, which, in turn, risks sowing the seeds of vendetta and the further destabilization of society. Finally, retributive penology is motivated by the premise that institutionalized punishment promotes deterrence by example. That is, not only is the offender punished but those who would follow in his criminal footsteps, witnessing his punishment, will be deterred from committing similar crimes. In some cases, there is a bonus – a sex offender incarcerated for life or executed for his crimes will not himself recidivate. We mention, parenthetically, an observation first made by John Money that certain paraphilias are the only mental illnesses deemed to merit the death penalty rather than psychiatric treatment in some jurisdictions.

With respect to perpetrators of sex offenses, the authors are not aware of any peer-reviewed research or literature directly addressing the issue of stress in the offender, although it seems equally axiomatic that both victims and offenders may experience toxic stress when the sex offending takes place. There have been limited studies of stress in prison populations, which may provide leads for research in this area. It is thought, for example, that inmates or corrections officers with a certain psychological makeup or privileged position are immunized against the stress of the prison setting to a greater degree than other inmates or corrections officers in the same setting.

Part of the difficulty in assessing the impact of stress on both victims and sex offenders is that neither

is a homogeneous group. In this article, we raise some issues relevant to stress in sex offenders and leave to others the parallel task of defining stress-related issues in the victims of sex offenses.

Definitional Considerations

Sex Offender

As we have pointed out, the term sex offense is a legal term. What constitutes a sex offense differs from jurisdiction to jurisdiction. As we pointed out in the preceding section, sex offenders are not a homogeneous group, with the sole exception of the fact that they have broken some law governing sexual behavior in a given culture or jurisdiction. It is sometimes not well understood that cross-cultural as well as intra-cultural considerations must be taken into account in defining sex offenses as well stress with respect to atypical sexual urges, fantasies, and behaviors.

For example, in some jurisdictions in the United States and in similarly less sexually tolerant foreign cultures, certain sexual behaviors such as premarital or extra-marital sexual contact, homosexual acts, cross-dressing, and heterosexual oral-genital or anal sexual contact are sex crimes and their practitioners are thus sex offenders. In virtually all cultures and jurisdictions, some sexual behaviors such as sexual contact with children (although the age of majority varies widely) are crimes and the individuals who engage in them are sex offenders as well.

Whether or not such criminal behaviors always, or even usually, engender stress depends on myriad considerations, including the degree of enforcement of the laws prohibiting the behavior, potential punishments, and whether individuals who engage in them find their own behavior personally acceptable (ego-syntonic) or unacceptable (ego-dystonic). Just as sex offenders are not a homogeneous group, the resultant stress from sex offending is not homogeneous.

Perhaps the only constant in the term sex offense and its equivalents in other cultures is that it is a legal construct. As such, it is not necessarily congruent with psychiatric or psychological views of these acts. Indeed, the differences between legal and psychiatric conceptualizations of sexual behaviors often leads to considerable dissonance and clouds the social debate about what should be done about sex offenders; they can lead to violent culture clashes, complicating considerably our understanding of stress as it relates to sex offending.

Phenomenology

Phenomenology, as we use the term here, is the personal, internal experience of the sexual fantasy or

behavior without respect to explanations for the behavior itself. Phenomenology, which has its roots in existential philosophy and, by extension, existential psychology, concerns itself with a scientific approach based on the phenomena themselves (here sexual drives, feelings, and motivated behaviors), without attempting to further explain them, as, for example, a psychodynamic approach might do. It also fails to embrace *in toto* the tenets and conventions of behaviorism. This theoretical approach has profound implications for treatment of “sex offenders.”

Phenomenology is premised on the concept that behavior is determined by the way a person perceives reality rather than on some external objective reality. Thus, phenomenology does not rely on attempts to explain or interpret in order to classify sex offending. Nor does it rely overly much on changing behaviors themselves with the expectation that changing behaviors will change behavior. As a theory of psychology, phenomenology draws heavily on the tenets of existential psychology, which posits that psychology should concern itself with the organism’s own experience of existence in the world. It draws heavily on the philosophical work of Karl Jaspers and the psychological application of that work by existential theorists such as Medart Boss, Ludwig Binswanger, and Viktor Frankl.

Paraphilias

Sex offenses and sex offenders are often classified as paraphilic or nonparaphilic.

The term, paraphilia, (from Greek *para-* beside + *philos* love) is an English translation of a term first proposed by Wilhelm Stekel in his book *Sexual Aberrations*, which first appeared in English about 1925. Reportedly, Stekel believed that a new term with less pejorative connotations than perversion (from Latin for turning around) would be helpful in examining and ameliorating these mental illnesses. Freud used the term, but it was not in widespread use in the psychiatric literature until the 1950s.

The *Diagnostic and Statistical Manual* (4th edn., text revision, DSM-IV-TR) of the American Psychiatric Association proposes that the “essential features of a paraphilia are recurrent, sexually arousing fantasies, sexual urges or behaviors generally involving 1) non-human objects, 2) the suffering or humiliation of oneself or one’s partner, or 3) children or other non-consenting persons, that occur over a period of at least 6 months” (Criterion A; 2000: 566). DSM-IV-TR suggests that for some individuals “paraphilic fantasies or stimuli are obligatory for erotic arousal and are always included in sexual activity.” For other individuals, paraphilic “preferences appear only

episodically (e.g., during periods of stress)” (2000: 566). Criterion B for paraphilias, according to the DSM-IV-TR, is that they “must cause clinically significant impairment in social, occupational or other important area of functioning” (2000: 566). Thus, the DSM-IV-TR definition of paraphilia is at variance with the definition that we proposed previously, in that behavior alone is sufficient to make a diagnosis. We insist on a definition of paraphilia that presupposes motivated behavior that is sexually driven by recurrent, intense sexual urges and fantasies.

As an example, consider the variety of motivations driving the behavior of genital exposure:

- Preparing to bathe, dress, urinate, or otherwise engage in the gamut of biologically or socially based needs ordinarily considered to be nonsexual.
- Engaging in nude sunbathing, swimming, or other nonsexual recreational pursuits alone or with consenting others in lawful locations.
- Permitting a genital examination or other procedure for medical reasons.
- Engaging in sexual behavior with oneself or with consenting others.
- Attempting to attract the attention of nonconsenting people with or without the intention to initiate sexual contact.
- Attempting to shock, embarrass, humiliate, punish, frighten, or harass a nonconsenting person.
- Engaging in a social or cultural protest or making a political statement.
- Responding to a dare, exposing oneself as a penalty in a game or as a requirement for consensual initiation into social group.
- Engaging in a marginally socially accepted behavior, such as streaking or flashing, or participating exposed in a parade, festival, or other activity in which others are likely to do the same thing.
- Modeling for sculpture, painting, photography, or other artistic endeavors such as making films or participating in theatrical performances, either for remuneration or for altruistic reasons.
- Stripping for remuneration at a club or prenuptial party.
- Being sexually assaulted or intimidated into exposing oneself.
- Submitting to a lawful strip search.
- Preparing to commit a sexual assault on a nonconsenting person.
- Exposing oneself secondary to disinhibition caused by exogenous substances.
- Exposing oneself in response to command hallucinations.
- Exposing oneself secondary to dementia or traumatic brain insult.

Surely, most of these instances of genital exposure cannot be considered paraphilic. Some are prosocial, whereas some are antisocial. Some have negative or neutral erotosexual valence, whereas some are highly erotic. Paraphilic behavior, influencing as it does the sexual-response cycle, is by definition erotosexual. Yet only a subset of the exposing behaviors listed here that have positive erotosexual valence might be motivated by recurrent, intense sexual urges and fantasies outside some presumptive or defined norm. Only those that satisfy this criterion can be considered paraphilic.

Etiology There is no known etiology of paraphilias, but some investigators believe there are associations between paraphilias and other life experiences. The most common association reported is between paraphilias and early childhood experiences. Theories change and track dominant schools of psychological thought. For example, when psychodynamic theory was the predominant psychiatric theory, fur fetishism was explained as a sequella of the birth experience, in which an infant became fixated on the pubic hair of the mother during childhood. In the light of present-day understanding, such an explanation seems unlikely. However, more satisfying explanations have not yet been forthcoming.

More recently, various researchers have postulated a relationship between the development of paraphilias and childhood physical or sexual abuse. Such theories have led to concepts such as the cycle of abuse, in which it is postulated that the abused becomes the abuser by some mechanism as yet not clearly delineated. There is currently considerable debate about the proposition that such abuse may have occurred in preverbal children and the memories recovered many years later. Empirical studies have not been kind to the cycle of abuse construct, although it is at the foundation of a number of still widely used treatment regimens.

Although a good statistical correlation between having been abused as a child and perpetrating abuse as an adult has not been demonstrated, in some sexually abusive individuals there is a considerable history of childhood sexual, physical, and/or emotional abuse or neglect. The recalled or sometimes corroborated sexual biographies of a great many paraphilic individuals contain experiences in which the patient's paraphilia seems closely linked to these experiences. For example, individuals who received frequent spankings, enemas, or even highly embarrassing physical examinations as children have sometimes reported that as adults these unpleasant experiences have become highly pleasurable with positive erotic valence and may be incorporated as obligatory or nonobligatory paraphilic components of their sexual-response

cycle. One possible explanation for this transformation may be the mechanism of opponent process theory of acquired motivation proposed by Richard Solomon and his colleagues, in which, like skydiving, an intensely fear-laden experience gradually becomes highly pleasurable, sought-after exhilarating activity. Other investigators have suggested that paraphilias are reinforced by masturbation to deviant fantasies. Unfortunately, all these ideas, as well as others, await solid empirical evidence. At this point, we can say with certainty only that the genesis of paraphilias remains largely unknown.

Prevalence There are in excess of 50 named paraphilias in the sexological literature. Some appear to be quite rare, whereas others, especially in their nonobligatory form, seem relatively common. The paraphilias most frequently coming to the attention of clinicians are pedophilia (which typically includes ephebophilia, although they are different paraphilias), voyeurism, and exhibitionism, according to DSM-IV-TR. This is hardly surprising, given that acting on these paraphilias is illegal in most jurisdictions, and individuals acting on these paraphilias are the most likely to seek clinical treatment, typically mandated by the judiciary. Given the distribution of pornographic materials with legal paraphilic content, for example, films and magazines devoted to transvestic fetishism, leather fetishism, or the milder forms of sadism and masochism, we might speculate that these paraphilias are among the more common. Yet sadism and masochism are relatively infrequently seen in clinical practice.

Erotic materials depicting other kinds of paraphilias, for example zoophilia, are typically suppressed. And although zoophilia is illegal in most jurisdictions, it seems to be less aggressively prosecuted, even when it comes to the attention of the authorities, than, say, sexual behavior involving children. It is difficult to extrapolate from any available data the prevalence of a given paraphilia or an all-inclusive prevalence of paraphilias in the American culture. DSM-IV-TR reports that, except for sexual masochism, with a sex ratio of 20 males to each female, paraphilias are almost never diagnosed in females. DSM-IV-TR further reports that approximately half of all individuals with paraphilia seen in clinics are married.

Treatment of Sex Offenders

In practice, the treatment of sex offenders may depend less on careful differential diagnosis than on the convictions that the treatment provider holds about sex offenders. Treatment providers with a behavioral view rely more heavily on psychological treatments

designed to change behaviors than do treatment providers who subscribe to a more medical model approach. These providers tend to use more pharmacologically based interventions than their behaviorist colleagues. The authors rely on an approach that takes advantage of an appropriate mix of interventions, following a careful differential diagnosis.

Psychological Treatments

The various psychological therapies, whether individual or group therapies, are designed to change behaviors through a variety of strategies including challenging patients' distorted thought and belief patterns (cognitive behavioral therapy), developing strategies to anticipate and resist deviant sexual cravings (relapse prevention), and replacing maladaptive behaviors with more functional behaviors (behavioral therapy). More traditional psychodynamic and psychoanalytic psychotherapy treatment modalities have been largely abandoned in the treatment of sex offenders because of their lack of demonstrated efficacy despite decades of attempts.

Behavior therapy Behavioral therapy is guided by learning theory, specifically social learning theory. In contrast to psychodynamic therapies, behavior therapies are primarily concerned with the aberrant behavior itself and not its underlying cause. That is, behavior therapy aims to decrease and extinguish deviant sexual arousal through a set of techniques, such as systematic desensitization, aversion therapy, biofeedback, minimal arousal conditioning with aversive conditioning, and covert sensitization. (Masturbatory satiation, a form of arousal reconditioning, is no longer widely used.)

Covert sensitization, a form of aversion therapy, has been widely used in the treatment of paraphilic patients. It is postulated that the pairing of deviant sexual fantasies with the mental image of its humiliating consequences (i.e., the aversive experience) will dissuade a patient from acting out sexually. In covert sensitization, deviant arousal or excitement is paired with a visualized distressing thought or fantasy. To give an example, a voyeur will be asked to imagine being taken into custody as soon as he begins to contemplate peeping into other people's windows.

In contrast to the aversive behavioral therapies, operant conditioning methods use positive reinforcers. For example, positive olfactory conditioning employs pleasant aromas with nondeviant sexual stimuli.

Cognitive-behavioral therapy Cognitive-behavioral therapy hypothesizes that paraphilias are maintained by distorted cognitions and reinforced by masturbation to inappropriate fantasy. The aim of cognitive

therapy is to change maladaptive thoughts and beliefs through techniques such as cognitive restructuring and thought stopping and to eliminate reinforcers that maintain distorted cognitions. The technique of cognitive restructuring teaches patients to identify, challenge, and ultimately replace erroneous (i.e., distorted) beliefs with adaptive and pro-social cognitions. Thought stopping is a technique that aims to decrease the frequency and duration of deviant sexual thoughts.

More often than not, a combination of one or more of these therapies is used. Victim empathy training has traditionally been an important component of all behavioral treatment and involves helping a patient take on the perspective of his victim(s). In addition, assertiveness and a variety of social skills training programs have been deemed to be important components in treatment programs, although recent research seems to indicate that empathy or social skills training have little or no impact on sexual recidivism in treated populations.

Relapse prevention A relapse is a recurrence of undesirable behavior after a period that has been free of the undesirable behavior. The term "relapse" is not synonymous with "recidivism" which indicates re-arrest for an illegal behavior. The objective of relapse prevention is to help a patient maintain behavioral changes. In order to reduce the risk of inappropriate sexual behavior, patients are taught to identify their deviant cycle and to develop strategies to implement when the cycle is triggered.

Group therapy Group psychotherapy is a widely accepted treatment modality used in the treatment of paraphilic and nonparaphilic sex offenders. It incorporates relapse prevention and cognitive-behavioral techniques, as well as empathy and social skills training. Group therapy creates a supportive milieu that is conducive to frank discussion and that provides guidance regarding effective relapse prevention strategies. It also encourages the development of a social support network and of healthy adult relationships. One of the primary advantages of group therapy over individual therapy is that it allows patients to be challenged by members of the group rather than by the therapist. This is important given that patients may respond and be more willing to change if challenged by one of their peers.

Effectiveness of psychological treatments The effectiveness of the psychological treatments in treating paraphilias is difficult to assess. One measure of treatment success has traditionally been recidivism. Some studies have concluded that these treatments

have positive effects; other studies have found minimal or no effect with behavioral therapies. The interpretation of these studies may be confounded by a number of variables such as non-standardized treatment delivery or heterogeneous populations. Also, studies of the treatment of sex offenders generally do not differentiate paraphilic from nonparaphilic offenders.

Nor is it clear that treatment delivered in one setting, say a prison, generalizes to another setting, such as the community. State-dependent learning, for example, may impact psychological treatments that depend on a psycho-educational approach. Relapse prevention, a widely used psychological treatment modality, may be less effective than previously believed. In one randomized clinical trial that compared the reoffense rates of patients in an inpatient relapse prevention treatment program with the reoffense rates in two untreated prison control groups, no significant differences among the three groups in rates of sexual or violent reoffending over an 8-year follow-up period were found.

Biological Treatments

The authors believe that with certain patients, for example those with dangerous paraphilias or those at acute risk of victimizing someone, pharmacological intervention should be the treatment option of first resort. Biologically based treatments should also be made available to paraphilic patients if, for example, cravings for deviant sexual activities become overpowering or when specific symptoms are not responsive to less invasive treatment modalities (e.g., behavioral therapy).

Surgery Among the biologically based treatments, we must differentiate between surgical and pharmacological interventions. Stereotaxic hypothalamotomy is only of historical interest. On the other hand, the orchiectomy (surgical removal of the gonads) data are particularly relevant in that they provide the basis for our understanding of the benefits of the currently used testosterone-lowering agents. Orchiectomy consistently lowers the rate of recidivism. Orchiectomy has been rendered largely unnecessary with the advent of the pharmacological treatment.

Pharmacotherapy For ethical and medical reasons, randomized, double-blind, placebo-controlled pharmacological treatment studies cannot be conducted with symptomatic paraphilic patients who reside in the community. Such studies could only be justified on patients with relatively innocuous paraphilias. Nevertheless, the number of medications used to treat paraphilias has been steadily increasing. These

medications can be divided into two general classes: those that act by lowering available androgens (e.g., progesterone derivatives and the gonadotropin releasing hormone analogs) and those that do not directly reduce androgen activity but reduce libido and/or sexual function as a side effect (e.g., some serotonin reuptake inhibitors). As with all pharmacological treatments, the choice of which medication to use is primarily based on the patient's presenting symptoms, his or her concomitant psychiatric/neurological disorders, and the results of the psychosexual and medical workup. A regrettable shortcoming of pharmacotherapy, however, is that it does not selectively reduce the risk for sex offending without generally impairing overall sexual functioning.

Concluding Remarks

There are a number of studies in the literature suggesting that treatment can be helpful, particularly in paraphilic samples. One such study reported rates of recidivism following treatment in a primarily paraphilic sample that were well below the rates reported in the world literature for comparable untreated cases. In another, a meta-analysis that reviewed data from 43 studies examining the sex offense recidivism rate for mixed sex offenders without differentiating between paraphilic and nonparaphilic patients found that recidivism, on average, was approximately 12% lower for treatment groups than for nontreatment groups.

Measuring treatment effectiveness presents significant problems. Recidivism, defined as some subset of involvement with the criminal justice system during or after the completion of treatment, is the most commonly used end point for determining treatment effectiveness in sex offenders. But not all paraphiles are sex offenders and not all sex offenders are paraphiles. Clearly, it is not possible to use recidivism as a measure of treatment efficacy with patients whose paraphilias are not illegal. Defining recidivism and dealing with important but largely unknown variables such as the base rate for reoffending and other methodological impediments greatly influence the interpretation of the available data and are central to answering questions about which treatment modalities work and which do not.

Sex offenses are prevalent and those motivated by paraphilia-driven phenomenology often constitute significant psychiatric disorders. Other, nonparaphilic sex crimes may have their roots in serious psychopathology as well. All too frequently, patients manifesting these conditions are simply ostracized, stigmatized, and punished when what is called for is enlightened psychiatric care.

Ignoring phenomenology and defining even observable manifestations of human sexuality in purely behavioral terms can only lead to egregious errors. Nowhere is this more apparent than in the arena of sex offender treatment. The phrase itself seems to us to be misleading, if not an oxymoron. With or without civil commitment statutes, clinicians are often called on to treat sex offenders. For example, a phenomenological view of rape implies that rape is not a monolithic sex offense but a highly variable one. Rape may be an opportunistic act, carried out by an individual without a sense of conscience. It may be the result of command hallucinations. It may also be paraphilic. It seems reasonable to assume, as in all psychiatric treatment, that how we approach the treatment of a rapist, or for that matter any sex offender, must depend to some degree on differential diagnosis, which, in turn, depends on the phenomenology underlying the behavior.

Medical Complications

Stress and Chronic Illness

Sickle Cell Disease-Related Stressors

Coping Styles and Sickle Cell Disease

Glossary

Sickle cell disease (SCD) An inherited blood disorder including sickle cell anemia, sickle cell hemoglobin disease, and sickle β -thalassaemia. SCD affects around 1 in 400 African Americans, and approximately 50,000 individuals have sickle cell anemia in the United States. SCD is also found in Europe, India, Africa, Central and South America, and the Caribbean.

Vaso-occlusive episodes Recurrent and painful crises are caused by the sickle hemoglobin molecules, which may stick together under low oxygen tension, distorting the red blood cells into a pathognomonic and rigid sickle shape and reducing their normal elasticity.

SCD, like all chronic illnesses, can be considered as a major stressor to which children and their families have to adjust by reducing the stresses associated with the condition and developing appropriate coping skills to ensure that the affected children and their families can lead a normal life.

Medical Complications

Vaso-occlusive crises caused by sickled red cells are responsible for chronic and acute damage to tissue and organs and cause recurrent and unpredictable

episodes of acute pain, often very violent, in the affected parts of the body, most usually the arms, legs, joints, and back, causing 91% of hospital admissions. Other complications include abdominal pain and enlargement of the liver or spleen, infections, delayed growth and onset of puberty, problems with pregnancy, priapism, avascular necrosis, and strokes, which may also occur in childhood. Effective clinical management requires medical and psychological skills. Medical treatment is mainly supportive and involves rapid and adequate analgesia, hydration, and treatment of any precipitating events such as infection and inflammatory conditions.

Stress and Chronic Illness

Wallander and Varni suggested that families with a chronically ill child are at greater risk of maladjustment because they are exposed to a greater number of stressful situations. These may happen to the child directly (e.g., missing school because of complications) or indirectly, affecting the family (e.g., marital disagreements and financial difficulties). They also suggested a set of factors associated with adjustment to chronic illness, including intrapersonal (e.g., functional independence), interpersonal (e.g., coping style of the family), and social-ecological (e.g., family functioning and socioeconomic status). This approach emphasizes the need to identify the specific stresses related to a disease and also generates the hypothesis that increased frequency and severity of stressors will result in poor adjustment. Adjustment could then be defined in terms of how well an individual deals with the typical stressful situations associated with a specific chronic illness.

Sickle Cell Disease-Related Stressors

For children and adolescents with SCD, the most frequent and severe stress is probably the experience of pain, both mild and severe; the uncertainty of painful crises; its adverse effect on their daily lives; and the risk of a sudden death. Pain crises and hospitalizations have been reported by children with SCD as

the most stressful aspects of their lives. SCD can disrupt school attendance and activities (e.g., sports), which may have a negative effect on their social life and academic performance. In adults with SCD, adjustment has been related more closely to life stress (e.g., financial and work) and social support. SCD can limit or disrupt a wide range of activities because exercise, cold exposure, and other factors can precipitate sickling.

However, family life and employment are the most significant areas of social life in adults with SCD. An increased personal responsibility for coping and financial status play important roles in coping with SCD, and most of those affected belong to ethnic groups that are already at a significant socioeconomic disadvantage. It has been suggested that the more psychosocial stressors within the family, the less effectively the SCD patient and the family cope with the condition and that families with more social support available appear to cope more favorably with the stressors associated with SCD.

Psychological research suggests that life stress and psychosocial adversity are the most likely precursors of maladjustment and psychopathology in adults with SCD. Thompson and colleagues found that over half of adults with SCD in their study met the criteria for poor adjustment, with 40 and 32% showing symptoms of depression and anxiety, respectively. Better adjustment was associated with lower levels of perceived daily stress, higher efficacy expectations about illness tasks, and less use of palliative coping and negative or passive coping strategies, but it was not associated with type of SCD or measures of severity. Family functioning was related to psychological status, with higher family support and lower family conflict and control among those with better adjustment.

Coping Styles and Sickle Cell Disease

Research has shown that active coping strategies (i.e., addressing stressors) are associated with good adjustment, whereas avoidance coping strategies (i.e., ignoring or avoiding stressors) are associated with poor adjustment. Passive strategies and negative thinking have been associated with lower activity levels and greater treatment requirements. Thompson and colleagues provided a transactional stress and coping model that views chronic illness as a potential stressor to which the individual and the family attempt to adapt. Thus, the transactional stress and coping model includes parameters that are illness-specific as well as common demographic and adaptational parameters that are assessed across illnesses.

Coping is hypothesized to be a function of the transactions of illness parameters, demographic

parameters, and adaptational processes. Illness parameters include type, severity, and age of onset. Demographic parameters include patient age, gender, and socioeconomic status. Adaptational processes include cognitive processes of stress appraisal; expectations of efficacy; and health locus of control, self-esteem, and causal attributions.

Thompson and coworkers found that the pain-coping strategies of children with SCD were characterized by negative thinking, which accounted for a 20% increment. Variables of the transactional stress and coping model accounted for 30% of the variance in child-reported symptoms and 45–49% of the variance in mother-reported behavior problems. Thompson and colleagues also found that higher levels of stress and lower levels of self-worth accounted for a significant portion of the variance in self-reported symptoms.

Future research needs to investigate illness-specific patterns of adaptation and to develop interventions aimed at enhancing methods of managing cognitive appraisals of illness-related stress.

Stress and Sleep Loss

Stress and Jet Lag

Stress and Shift Work

Glossary

Endogenous circadian rhythm

An oscillation with a period of approximately 24 h generated by a pacemaker mechanism located in the suprachiasmatic nuclei of the hypothalamus. This endogenous rhythm persists in the absence of any periodic variations in the environment (e.g., light–dark cycle and rest–activity cycle).

Jet lag syndrome

The malaise experienced by the majority of travelers during the days following a flight across time zones. The syndrome usually includes symptoms of daytime fatigue, difficulties initiating and maintaining sleep, deterioration of mood, vigilance, and cognitive function and may also involve gastrointestinal disorders. The syndrome is believed to result from the misalignment between bodily rhythms and the 24-h periodicities in the environment.

Sympathetic and parasympathetic tone

The autonomous nervous system plays a crucial role in the stress response and includes the sympathetic and parasympathetic nervous systems. Nearly all organs receive both sympathetic and parasympathetic inputs. During stress, sympathetic activation is increased and thus the balance of sympathetic versus parasympathetic control (i.e., the sympatho-vagal balance) is shifted toward higher sympathetic as compared to parasympathetic control.

The evolution of industrial society has been associated with major changes in the behavioral control of the sleep–wake cycle and in the environmental light–dark cycle. The availability of electrical lighting has made extended activity hours and around-the-clock operations possible. Misalignments among

endogenous circadian rhythms, sleep–wake cycle, and light–dark cycle are highly prevalent in the working population and also affect millions of travelers who use rapid air transportation across time zones. While it is the common perception that sleep loss, jet lag, and shift work are stressful, there are remarkably few studies of either subjective or objective markers of stress in these conditions.

Stress and Sleep Loss

Voluntary sleep curtailment is a hallmark of modern society. In the United States, normal sleep duration has decreased from approximately 8.5 h in 1960 to an average of less than 7.0 h in 2006. To maximize the time available for work and leisure activities, it has become socially desirable to curtail sleep to the shortest amount tolerable. Around-the-clock operations imply chronic partial sleep loss for the large population of shift workers and the repeated occurrence of total sleep deprivation for key personnel.

Although multiple studies have shown that total sleep deprivation or repeated sleep curtailment by as little as 2–3 h per night results in marked decrements in mood and performance, subjective indices of stress in subjects studied in the laboratory remain generally low. In particular, self-ratings on scales of tense and nervous remain stable across extended periods of total sleep deprivation under comfortable and sedentary laboratory conditions. Similarly, ratings of perceived stress remain low and stable in subjects submitted to up to 1 week of partial sleep deprivation in the laboratory. Sleep deprivation does not appear to be a classical stressor, resulting in an immediate activation of the sympathetic nervous system or in the rapid release of stress hormones. Indeed, the only known immediate effect of acute total sleep deprivation on physiological function is the absence of responses normally elicited by sleep onset or awakening from sleep, such as declines and increases in heart rate. However, sleep loss, even when only partial, appears to be associated with an alteration in the regulation of the hypothalamic–pituitary–adrenal (HPA) axis, the major neuroendocrine transducer of stress. Indeed, in sleep-deprived subjects, the normal morning-to-evening decline of blood levels of the stress hormone cortisol is slowed down and, as a result, evening cortisol levels are elevated. This alteration suggests that the rate of recovery of the HPA axis from exogenous stimulation by stressors may be affected by sleep loss. An elevation of cardiac

sympathetic activity occurs following recurrent sleep restriction. Thus, sleep loss may indeed result in an activation of the major biological mechanisms involved in the stress response. However, even though sleep loss appears to be interpreted biologically as a stressor, subjectively, the subjects do not seem to experience sleep restriction as stressful since they consistently rate their perceived stress as low, irrespective of bedtime duration. This apparent dissociation between the biological and psychological response to sleep loss may only occur in the unchallenging environment of the laboratory. The combination of increased sympathetic nervous activity and elevated evening cortisol levels in a state of sleep debt may play a role in the deterioration of parameters of glucose tolerance that is associated with short sleep.

Stress and Jet Lag

Jet lag syndrome is a condition of desynchrony between the near 24-h (i.e., circadian) endogenous rhythm generated in the suprachiasmatic nuclei of the hypothalamus and the external light-dark and rest-activity cycles that arises following rapid transportation across time zones. The syndrome usually includes symptoms of fatigue, sleep disturbances, reduced cognitive and psychomotor performance, and gastrointestinal tract disorders. The syndrome subsides as adaptation to local time is achieved. The 24-h secretory rhythms of hormones of the HPA axis adapt at a slower rate (averaging 1 day per hour of time difference) than diurnal variations in catecholamine levels or sympatho-vagal tone. Adaptation to jet lag nearly always involves some degree of sleep loss and therefore alterations of HPA regulation typical of sleep deprivation are to be expected.

Stress and Shift Work

To meet the demands of around-the-clock operations, millions of shift workers live in a condition of chronic sleep debt and desynchrony between endogenous rhythms and environmental periodicities. Indeed, studies have shown that shift workers get significantly less sleep per scheduled sleep period than daytime workers, with many sleeping on average less than 5 h per work day. In contrast to occasional jet lag, shift work is a major health hazard, involving an increased risk of cardiovascular illness, gastrointestinal disorders, psychosocial complaints, sleep disturbances, substance abuse, reduced immune function, and infertility.

Shift workers thus live in a situation of conflicting zeitgebers, which almost never allow a complete shift of the circadian system. Indeed, several studies have

shown that workers on permanent or rotating night shifts do not adapt to these schedules, even after several years. In particular, the temporal profile of secretion of the stress hormone cortisol shows little, if any, adaptation to the work schedule. There is evidence for increased blood pressure and increased sympathetic versus parasympathetic tone during night shift as compared to day shift activity in emergency rooms of hospitals. Under chronic conditions, such disturbances could result in cardiovascular illness.

Normal Sleep
Sleep Disorders
Sleep, Sleep Disorders, and Physical and Emotional Stress
Sleep and Stress System
Conclusion

Glossary

Addison's disease An endocrine disease that is associated with aldosterone and cortisol (hormones) by the adrenal glands.

Apnea Cessation of breathing lasting at least 10 s.

Cataplexy A brief and sudden loss of muscle control without loss of consciousness usually precipitated by strong emotions.

Continuous positive airway pressure (CPAP) A small apparatus which through a soft plastic mask blows air gently through the nose into the throat to keep the airway open.

Cosinor analysis Least square approximation of time series using a cosine function of known period.

Dihydroxy-phenylacetic acid (DOPAC) A metabolite of dopamine.

Dihydroxy-phenylglycol (DHPG) A metabolite of norepinephrine produced by the action of the enzyme monoamine oxidase (MAO) which can be measured in urine.

Hypersomnia Disorder of excessive diurnal and nocturnal sleep.

Hypnagogic Occurrence of an event while drifting into sleep.

Hypoxia

A pathological condition in which the body as a whole (generalized hypoxia) or region of the body (tissue hypoxia) is deprived of adequate oxygen supply.

Of unknown causation.

Idiopathic Microneurography

A method to record the traffic of impulses in human nerves with percutaneously inserted needle electrodes.

Narcolepsy

Sleep disorder associated with excessive daytime sleepiness, involuntary daytime sleep episodes, disturbed nocturnal sleep, and cataplexy (sudden loss of muscle tone).

Parasomnia

Is any sleep disorder such as sleepwalking, teeth grinding, night terrors, rhythmic movement disorder, rapid eye movement (REM) behavior disorder, restless leg syndrome, and sleep talking, characterized by partial arousals during sleep or during transitions between wakefulness and sleep.

Polysomnography

The continuous and simultaneous recording of physiological variables during sleep, e.g., electroencephalography, electrooculography, electromyography, electrocardiography, respiratory flow, etc.

Pulsatile analysis

A global analysis of the mechanical function of the cardiovascular system, including the determinants of cardiac output.

Slow-wave sleep (SWS)

Sleep characterized by electroencephalogram waves of duration slower than 4 Hz and high amplitude.

Stage rapid eye movement (REM) sleep

The stage of sleep with highest brain activity characterized by enhanced brain metabolism and vivid dreaming.

Sleep appears to be an important element in maintaining equilibrium or homeostasis that is vital for the survival of living organisms. In this article, we review the association between sleep, sleep disorders, and stress, which has been defined as a state of disharmony, or threatened homeostasis.

Normal Sleep

Humans spend at least one-third of their lives asleep, yet there is little understanding of why we need sleep and what mechanisms underlie its capacities for physical and mental restoration. However, there has been a significant increase of empirical knowledge that is useful in the evaluation and management of most sleep complaints and their underlying disorder.

The interaction of circadian effects, i.e., usual time to go to sleep and amount of prior wakefulness (homeostatic response), determines the onset and amount of sleep. Natural sleep–wake rhythms cycle at about 25 h rather than coinciding with the solar 24-h schedule. As a result, many people depend on external cues to keep their diurnal cycle on time. The normal diurnal clock resists natural changes in its pattern by more than about 1 h per day, which explains the sleep difficulties that usually accompany adaptation to new time zones or switches in work shifts.

Individuals differ considerably in their natural sleep patterns. Most adults in nontropical areas are comfortable with 6.5–8.0 h daily, taken in a single period. Children and adolescents sleep more than adults, and young adults sleep more than older ones. Normal sleep consists of four to six behaviorally and electroencephalographically (EEG) defined cycles, including periods during which the brain is active (associated with rapid eye movements, called REM sleep), preceded by four progressively deeper, quieter sleep stages graded 1–4 on the basis of increasingly slow EEG patterns. Slow-wave sleep (SWS; also referred to as deep sleep; stages 3 and 4) gradually lessens with age and usually disappears in the elderly.

Sleep Disorders

Sleep disorders are common in the general population and are associated with significant medical, psychological, and social disturbances. Insomnia, the most common sleep disorder, most often reflects psychological disturbances. Excessive daytime sleepiness is the predominant complaint of most patients evaluated in sleep disorders clinics and often reflects organic dysfunction. Narcolepsy, idiopathic hypersomnia, and sleep apnea are the most common disorders associated with excessive daytime sleepiness. Narcolepsy and idiopathic hypersomnia are chronic brain disorders with an onset at a young age; sleep apnea occurs predominantly in middle-aged men and (to a lesser degree) women and is associated with obesity and cardiovascular complications. The parasomnias, including sleepwalking, night terrors, and nightmares, have benign implications in childhood but often reflect psychopathology or significant stress in adolescents and adults and organicity in the elderly.

Sleep, Sleep Disorders, and Physical and Emotional Stress

“Stress is life and life is stress” in Hans Selye’s words. If it is a fact that there is no life without stress, it is also true that there is no life without sleep. Thus, it is not surprising that the association between sleep and physical and emotional stress has been long recognized. Hippocrates observed early on the relationship between mental and physical health and sleep and stated that sleeplessness is a sign of pain and suffering and may lead to mental illness while sleeping during the day (daytime sleepiness) is an indication of illness. Also, sleep has been an ancient remedy in the hands of physicians to combat emotional or physical stress, e.g., infection.

Acute or short-term sleep disturbance is usually associated with a variety of situational stresses (work-related, interpersonal, or financial difficulties) or with medical problems such as pain, cardiopulmonary or gastrointestinal disorders, or the febrile prodromes to influenza. Various drugs, including those that humans have been using for hundreds of years to decrease stress and dysphoria such as alcohol, nicotine, and caffeine, can affect adversely the quantity and quality of sleep. Stressful life events at the onset of sleep disorders are quite common, particularly in those disorders that appear to be of emotional origin, such as insomnia. It has been found that 75% of the chronic insomniacs had experienced some stressful life event at about the time insomnia began. Stressful life events are present, although to a lesser degree compared to insomniacs, in other sleep disorders, such as narcolepsy or sleep apnea, or adult sleepwalking, night terrors, and nightmares. The presence of stressful life events at the onset of organic disorders, such as narcolepsy or sleep apnea, is considered coincidental. However, it is interesting to note that, for example, it has been proposed that in narcolepsy it is the combination of genetic factors and stress, including emotional stress, which leads to the manifestation of the disorder. In this respect, a recent study showed that a majority of people with narcolepsy had a stressful life event at onset of their illness.

Psychological distress appears to be quite common among patients with sleep disorders. In some of these disorders, such as chronic insomnia or adult parasomnias, it appears to be primary or etiologic. In other sleep disorders, such as sleep apnea, narcolepsy, or idiopathic hypersomnia, it appears to be secondary or reactive to the chronic physical problems associated with the sleep disorder. Furthermore, it has been reported that in insomniacs, it is not only stress, but also how they handle stress that leads to chronic difficulties in initiating and maintaining

sleep. In particular, insomniacs handle external stress and conflict by internalization of their emotions which results in a combination of emotional arousal and physiological activation. This mental and physiological hyperarousal leads to difficulty in initiating sleep, whether at the beginning of the sleep period or when returning to sleep following awakening. Fear of sleeplessness and performance anxiety further intensifies the emotional arousal. All of these factors through behavioral conditioning lead to a vicious circle that perpetuates insomnia.

Because of the high frequency of emotional distress associated with sleep disorders, stress management techniques are routinely recommended to all sleep-disorder patients. Specifically, in insomnia, besides recommending sleep hygiene measures, medication, or psychotherapy, a series of stress management measures are routinely recommended, such as: recognizing the association between stressful events and sleeplessness; ventilating conflict and anger to avoid internalization of emotions; addressing daily worries a few hours before bedtime; becoming tolerant of occasional sleeplessness; avoiding rumination over sleep difficulty; and relaxation techniques. Increasing empirical evidence suggests that cognitive behavioral therapy (CBT) for insomnia is the most effective non-pharmacological approach in the management of chronic insomnia. Besides using educational and behavioral techniques, CBT involves cognitive restructuring that aims at identifying and altering faulty beliefs and attitudes about sleep that in themselves are believed to perpetuate the vicious cycle of insomnia, fear of sleeplessness, emotional arousal, and further sleep disturbance. However, the CBT approach does not address long-term personality patterns such as internalization of psychological conflict and inhibition of emotions associated with insomnia. In the sleep disorders of organic origin, such as narcolepsy or sleep apnea, supportive therapy, including educating and advising patients and their families gently but honestly about the nature of the chronic disorder and that the symptoms are not under voluntary control, is of utmost importance. Furthermore, helping the patient to adjust his or her lifestyle to the changes imposed by the sleep disorder, i.e., sleep or cataplectic attacks in narcolepsy, or enhancing his/her compliance to the chronic use of cumbersome and often, anxiety-provoking therapies, such as continuous positive airway pressure (CPAP) in sleep apnea, is an important dimension of the overall management of the sleep-disorder patient.

Sleep disturbance is a very frequent symptom in most of the psychiatric disorders. Depression, anxiety disorders, and acute onset schizophrenia are frequently associated with sleep disturbance. Depression, in

particular melancholia, is associated with early morning awakening, while sleep loss is the early sign of an acute onset schizophrenia or an early sign of relapse. In contrast, sleep disturbance or sleep loss can lead to mental illness. For example, it has been reported that chronic insomnia is associated with a higher incidence of major depression. Also, acute sleep loss can lead to a manic episode in a patient with bipolar disorder. Thus, it is not surprising that sleep therapy or hypnotherapy was very common in the practice of mental health professionals in the nineteenth and early twentieth centuries. Today, the improvement of the quality and quantity of sleep of a person under emotional distress is one of the therapeutic priorities of the practicing clinician.

Sleep and Stress System

In mammalian organisms, including humans, the stress system consists of components of the central nervous system (CNS), including: the corticotropin-releasing hormone (CRH) neurons of the hypothalamic paraventricular nucleus; and several, mostly norepinephric nuclei of the brain stem, and their peripheral limbs, the hypothalamic-pituitary-adrenal (HPA) axis and the peripheral autonomic system, whose main function is to maintain homeostasis, both in the resting and stress states.

Normal Sleep and Stress System

Although the association between stress and sleep has been noticed for hundreds of years, a more systematic and scientifically based approach in the relation between sleep and stress system has only existed since the 1980s. It was in 1983 that Dr. Weitzman and his colleagues reported that sleep, in particular SWS, appears to have an inhibiting influence on the HPA axis and cortisol secretion ([Figure 1](#)). Since then, several studies have replicated this finding. In a reverse mode, activation of the HPA axis and central administration of CRH can lead to arousal and sleeplessness. In normal sleepers, wakefulness and stage 1 sleep (light sleep) accompany cortisol increases, while SWS is associated with declining plasma cortisol levels. In addition, in healthy people, induced sleep disruption (continuous arousals) is associated with significant increases of plasma cortisol levels. Furthermore, mean plasma cortisol level was significantly higher in a group of subjects with a shorter total sleep time than another group with a longer total sleep time. Finally, it has been suggested that the effect of aging on the levels and diurnal variation of human adrenocorticotrophic activity could be involved in the etiology of poor sleep in the elderly.

Figure 1 A simplified, heuristic model of the interactions between central and peripheral components of the stress system with sleep and REM sleep. CRH–ACTH–cortisol and LC/NE systems are two main arousal systems that their activation leads to wakefulness. NonREM sleep is associated with an inhibitory effect on these two wakefulness promoting systems, whereas during REM there is an activation of both limbs of the stress system. ACTH, corticotropin; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; GH, growth hormone; LC/NE symp sys, locus ceruleus-norepinephrine/sympathetic system. A solid line denotes promotion/stimulation; a broken line denotes disturbance/inhibition.

REM sleep, which is a state of CNS activation that resembles unconscious wakefulness (paradoxical sleep), appears to be associated with a higher activity of the HPA axis (Figure 1). An early study showed that urinary 17-hydroxy corticoids were increased during REM epochs in urological patients. One study in healthy, normal sleepers showed that the amount of REM sleep was positively correlated with 24-h urinary free-cortisol (UFC) excretion. These results are consistent with the co-existence of stress system activation, and REM sleep increases in patients with melancholic depression. In rats, chronic mild stress resulted in disruption of REM sleep, including a reduced latency to the onset of first REM period, providing support for the validity of the proposed association between stress and mechanisms underlying endogenous depression, including REM sleep alterations.

Although the effects of sleep on the sympathetic nervous system have been studied less frequently, it appears that in humans during sleep, catecholaminergic activity is decreased (Figure 1). In particular, catecholaminergic activity appears to be suppressed

during SWS, while there is an activation of the sympathetic nervous system during REM sleep. It has been found that in healthy, normal sleepers, the amount of REM sleep correlated to 24-h excretion of urinary catecholamines while sympathetic-nerve activity measured using microneurography, was elevated during REM sleep. Interestingly, in rats, locus ceruleus (LC) neurons fire most frequently during waking, less during nonREM (NREM) sleep, and are silent during paradoxical sleep.

The stress system is closely linked with immune responses. In particular, three pro-inflammatory cytokines (tumor necrosis factor- α (TNF- α), interleukin (IL)-1, and IL-6) have a strong stimulating effect on HPA axis (Figure 1). Glucocorticoids, the endproducts of the HPA axis, inhibit the production of all three cytokines, while catecholamines, the other products of the stress system, stimulate IL-6 secretion. In animals, several studies have demonstrated the potential role of these cytokines, particularly IL-1 and TNF- α in sleep regulation. In humans, these cytokines appear to be increased at nighttime. A study in young, healthy, normal sleepers showed that the amount and

quality (depth) of sleep correlated negatively with the overall daytime secretion of IL-6. These data suggest that a good night's sleep is associated with decreased secretion of IL-6, a good sense of wellbeing, and that good sleep is associated with decreased exposure of tissues to the pro-inflammatory and potentially detrimental actions of IL-6.

The role of corticotropin-releasing hormone in sleep-wake regulation CRH, which is produced and released from parvocellular neurons of the paraventricular nucleus, is the key regulator of the HPA axis. Release of CRH is followed by enhanced secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary and cortisol from the adrenal cortex. CRH exerts various influences on behavior, including wakefulness and sleep.

Several studies in animals have shown that intracerebroventricular administration (ICV) of CRH induces increased waking. Also, specific CRH receptor blockade reduces spontaneous awakening and rat strains deficient in the synthesis and secretion of hypothalamic CRH spend less time awake than do control counterparts. Finally, CRH concentration in the brains of rats exhibits circadian fluctuations and is highest when rats are most active. Several reports indicate that CRH is excitatory in the LC, hippocampus, cerebral cortex, and some portions of the hypothalamus. Spontaneous discharge rates in the LC are highest during arousal and lowest during sleep. Also, it has been reported that the brain β_1 -adrenergic system is involved in the restraint stress-induced increase in arousal in rats.

In humans, the majority of studies suggest that the sleep of young individuals is rather resistant to the arousing effects of CRH. In contrast, middle-aged individuals responded to an equivalent dose of CRH with significantly more wakefulness and suppression of SWS compared to baseline. Based on these findings, we concluded that middle-aged men show increased vulnerability of sleep to stress hormones, possibly resulting in impairments in the quality of sleep during periods of stress. These findings suggest that changes in sleep physiology associated with middle-age play a significant role in the marked increase of prevalence of insomnia in middle-age. Also, peripheral administration of CRH is associated with REM suppression, which is stronger in the young than in the middle-aged. The administration of ACTH and its analogs in humans has been associated with general CNS activation consisting of a decreased sleep period time and sleep efficiency, and an increase of sleep latency. Continuous administration of ACTH produced a marked reduction in REM sleep.

Arginine vasopressin (AVP) is a peptide which acts as a co-factor of CRH in the activation of the HPA system. Several experiments in rats have suggested that the continuous administration of AVP causes sleep disturbance.

Steroid effects on sleep The administration of glucocorticoids has been reported to be associated with a robust suppression of REM sleep (Figure 1). Also, in some studies, it has been reported that the continuous or pulsatile nocturnal administration of cortisol paradoxically was associated with a modest increase of SWS in addition to the well-established decrease of REM sleep. The opposite effects of cortisol on SWS compared to CRH are believed to be mediated by a feedback inhibition of CRH from cortisol. In contrast, the glucocorticoid antagonist, mifepristone (RU-486), led to a significant worsening of sleep in normal controls. The administration of mineralocorticoids is not associated with significant changes of sleep structure.

A study in patients with Addison's disease recently demonstrated that an evening replacement dose of hydrocortisone was necessary for proper expression of REM sleep (*vide infra*) suggesting that glucocorticoids have some permissive action for this sleep parameter, possibly reflecting an inverse u-shaped dose-response curve.

Interestingly, in clinical practice, the use of glucocorticoids is associated with sleep disturbance. In fact, in a multicenter study in which steroids were used on a short-term basis, sleep disturbance was one of the most common side effects.

Aging, HPA axis, and sleep Old age is associated with marked sleep changes consisting of increased wakefulness, minimal amounts of SWS, declining amounts of REM sleep, and earlier retiring and rising times. Some studies have shown that older adults have elevated cortisol levels at the time of the circadian nadir and have higher basal cortisol levels than younger adults. It is difficult to discern whether the latter changes are associated with aging or increased medical morbidity common in this group. It has been suggested that the effect of aging on the levels and diurnal variation of human adrenocorticotrophic activity could be involved in the etiology of poor sleep in the elderly. Higher evening cortisol concentrations are associated with lower amounts of REM sleep and increased wakefulness. More recently, it was shown that older women without estrogen replacement therapy (ERT), when subjected to mild stress, showed greater disturbances in sleep parameters than women receiving ERT, suggesting that female hormones protect women's sleep from external stressors.

Sleep Deprivation and Stress System

If sleep is important for our sense of wellbeing, then it is conceivable that sleep deprivation represents a stress to humans and should be associated with activation of the stress system. However, several studies that have assessed the effects of one night's sleep deprivation on the HPA axis have shown that cortisol secretion is either not or minimally affected by sleep following prolonged wakefulness. Two studies have reported somewhat antithetical results, with the one study showing that cortisol secretion is elevated the next evening following sleep deprivation, and the other study showing a significant decrease of plasma cortisol levels the next day and recovery night. The study that showed decrease of plasma cortisol levels following sleep loss indicated that this inhibition of the HPA axis activity was associated with an enhanced activity of the growth hormone axis. The finding that sleep deprivation leads to lower cortisol levels postdeprivation (primarily during the subsequent night of sleep) suggests that lowering the level of HPA activity, which is increased in depression, may be the mechanism through which sleep deprivation improves the mood of depressed individuals. Prolonged sleep deprivation that results in death is associated with increased plasma norepinephrine levels, and higher ACTH and corticosteroid levels at the later phase of sleep deprivation. It is postulated that these increases are due to the stress of dying rather than to sleep loss.

A recent study demonstrated that a week of partial sleep restriction did not affect significantly the 24-h cortisol secretion either in men or women. However, there was a significant effect in terms of the circadian secretory pattern of the hormone as indicated by the significant time effect, and the time and gender interaction effect. Specifically, the peak cortisol secretion in the morning was lower after sleep restriction than baseline and this difference was stronger in men than in women. In both genders, the peak of cortisol secretion was shifted by 2 h earlier than baseline (08.00 versus 06.00). Sleep restriction did not affect significantly the nadir value of cortisol secretion, neither the afternoon, nor evening presleep levels.

The inconsistency in cortisol secretion after total or partial sleep loss may be explained by methodological differences in these studies, i.e., nonstressful deprivation is not associated with increased cortisol secretion. Also, the higher evening cortisol levels reported in studies where sleep was curtailed at the beginning of the night may represent a change of the 24-h-secretory pattern, e.g., a shift of the nadir point later at night.

Although sleep deprivation appears to have beneficial effects on the mood of depressed individuals, in

healthy individuals, sleep deprivation leads to next-day fatigue and somnolence, decreased concentration and attention, and increased vulnerability to accidents. These effects appear to be mediated partially by the increased levels of IL-6, which is related to the stress system. It has been shown that following sleep deprivation, there is an increase of IL-6 levels during the daytime and a decrease during the first night of sleep following sleep deprivation. The increased levels of IL-6 during the daytime can explain the somnolence and fatigue experienced by the individuals after one night's sleep loss, whereas the nighttime undersecretion of IL-6 might be responsible for the better quality (depth) of their sleep. The exact mechanisms of this elevation are not known. However, alterations of the stress system following sleep deprivation may be responsible for this elevation. For example, the decreased levels of cortisol postdeprivation and/or possible increase of catecholaminergic activity can lead to elevation of plasma IL-6 levels. It has been shown that sleep deprivation in humans appears to enhance norepinephrine and dopamine activity.

Sleep Disorders and Stress System

Although sleep disorders/disturbances with their various physical and mental effects on the individual should be expected to affect the stress system, information regarding the effects of sleep disorders/disturbances on this system is lacking.

Insomnia and stress system Insomnia, a symptom of various psychiatric or medical disorders, may also be the result of an environmental disturbance or a stressful situation. When insomnia is chronic and severe, it may itself become a stress that affects the patient's life so greatly that it is perceived by the patient as a distinct disorder itself. Either way, as a manifestation of stress or a stressor itself, insomnia is expected to be related to the stress system. There is a paucity of data regarding the activity of the stress system in insomniacs. Few studies have measured cortisol levels in poor sleepers or insomniacs, and those results are inconsistent. The majority of these studies reported no difference between controls and poor sleepers in 24-h cortisol or 17-hydroxy steroid excretion. In a study in 15 young adults with insomnia, it was demonstrated that 24-h UFC levels were positively correlated with total wake time ([Table 1](#)). In addition, 24-h urinary levels of catecholamines and their metabolites, dihydroxyphenyl glycol (DHPG), and 3,4-dihydroxy-phenylacetic acid (DOPAC) were positively correlated with percent stage 1 sleep and wake time after sleep onset. Norepinephrine tended to correlate positively with percent stage 1 sleep and

Table 1 Sleep disorders and the stress system

Insomnia	Increased 24-h secretion of ACTH-cortisol, more intense in the evening; positive correlations between 24-h UFC and urinary catecholamines and polysomnographic indices of severity of the disorder
Sleep apnea	Increased excretion of urinary catecholamines; increased nighttime plasma catecholamines; increased daytime plasma IL-6 and TNF- α levels; mild hypercortisolemia compared to obese controls
Narcolepsy	Increased daytime plasma IL-6 and TNF- α levels
Idiopathic hypersomnia	Mild hypocortisolism; enhanced ACTH secretion to exogenous CRH; central CRH deficiency

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; IL-6, interleukin-6; TNF- α , tumor-necrosis factor- α ; UFC, urinary free-cortisol.

wake time after sleep onset and negatively with percent SWS. It was concluded that in chronic insomnia, the activity of both limbs of the stress system, i.e., the HPA axis and the sympathetic system, relates positively to the degree of objective sleep disturbance. However, in this study also, the total amount of the 24-h UFC or catecholamines excretion was not different from normative values. The results on the positive correlation between urinary catecholamines and polysomnographic indices of sleep disturbance in chronic insomnia are consistent with previous studies that showed elevated urinary catecholamines in chronically stressed subjects who experience sleep disturbance or in healthy subjects whose sleep was affected by nocturnal aircraft noise.

In a recent controlled study in which objective sleep testing and frequent blood sampling was employed, 24-h ACTH and cortisol plasma concentrations were significantly higher in people with insomnia than matched healthy controls. Within the 24-h period, the greatest elevations were observed in the evening and first half of the night. Also, people with insomnia with a high degree of objective sleep disturbance (sleep time <70%) compared to those with a low degree of sleep disturbance secreted a higher amount of cortisol. Pulsatile analysis revealed a significantly higher number of peaks per 24 h in insomniacs than in controls ($p < 0.05$), while Cosinor analysis showed no differences in the circadian pattern of ACTH or cortisol secretion between people with insomnia and controls. Thus, insomnia is associated with an overall increase of ACTH and cortisol secretion, which, however, retains a normal circadian pattern. Also, this increase relates positively to the degree of objective sleep disturbance. These findings are consistent with a disorder of CNS hyperarousal rather than one of sleep loss, which is usually associated with no change or a decrease in cortisol secretion, or a circadian disturbance. Two recent studies found that cortisol was elevated in primary insomnia with objectively documented sleep disturbance during the evening and nighttime. However, another study found that people with insomnia without evidence of objective

sleep disturbance did not report differences from controls. These findings suggest that objective sleep disturbance may be a useful index of the biological severity of the disorder.

Chronic activation or dysregulation of the stress system may play a significant role in the poor mental and physical health associated with chronic insomnia. Insomnia is associated with a higher risk of development of psychiatric disorders, such as major depression and anxiety disorders. Also, people with insomnia tend to have more health complaints than normal controls, both as children and adults, and they do appear to have poorer health in other respects. Psychosomatic-type illnesses, such as allergy, asthma, colitis, hypertension, migraine headaches, and ulcers, are reported by about twofold more people with insomnia than controls. Consistent with the above finding, a recent study that used a large general random sample of men and women (1754 people) reported that insomnia is independently associated with medical disorders such as hypertension. Also, nonspecific physical symptoms, such as headache, diarrhea, constipation, stomach discomfort, palpitations, shortness of breath, nonspecific pain, tiredness, and weakness, are also more common in people with insomnia. It can be hypothesized that these physical complaints, including those labeled as psychosomatic, reflect the chronic effects of an activation/dysregulation of the stress system in various body organs and functions. Furthermore, these data suggest that the therapeutic goal in insomnia should not be just to improve the quality or quantity of nighttime sleep. Rather, they suggest that the common practice of prescribing hypnotics only for patients with chronic insomnia at most is of limited efficacy. Sedative antidepressants alone or in combination with the newer antidepressants, e.g., selective serotonin reuptake inhibitors (SSRIs), appear to have a normalizing effect on measures, i.e., cortisol. Furthermore, the focus of psychotherapeutic and behavioral modalities, including sleep hygiene measures, should not be to just improve the emotional and physiological state of the people with insomnia

pre- or during sleep, but rather to decrease the overall emotional and physiologic hyperarousal and its underlying factors, present throughout the 24 h sleep-wake period. Finally, objective measurements of sleep using simpler methods such as actigraphy may prove useful in predicting the severity of the disorders and, therefore, the urgency for medical intervention.

Disorders of excessive daytime sleepiness and stress system Obstructive sleep apnea, the most common sleep disorder associated with excessive daytime sleepiness and fatigue, is associated with nocturnal hypoxia and sleep fragmentation. The latter conditions should be expected to be associated with an activation of the stress system. Indeed, it has been shown that urinary catecholamines, as well as plasma catecholamines measured during the nighttime, are elevated in people with sleep apnea compared to controls (Table 1). Also, using microneurography, it has been shown that obstructive apneas are associated with a surge of sympathetic nerve activity. It has been proposed that sympathetic activation in sleep apnea is one of the mechanisms leading to the development of hypertension, a condition commonly associated with sleep apnea. With similar logic, it was expected that sleep apnea would be associated with an activation of the HPA axis also. However, the few studies that have assessed the plasma cortisol levels in people with sleep apnea have failed to show any differences from controls. Also, no differences were reported in the excretion of cortisol following the abrupt withdrawal of CPAP, a definitive treatment for sleep apnea. However, whether these results represent an adaptation of the HPA axis to a chronic physical stress or are a result of incomplete assessment of the HPA axis, remains open.

Narcolepsy and idiopathic hypersomnia are two primary sleep disorders of bipolar disorders currently treated with medication such as stimulants and modafinil. The association of the two other organic disorders of excessive daytime sleepiness, narcolepsy and idiopathic hypersomnia, with the stress system has not been assessed. Preliminary data from a study that assessed the responsiveness of plasma cortisol and ACTH to the exogenous administration of CRH in individuals with idiopathic hypersomnia indicated reduced 24-h UFC levels compared to controls while ACTH response to CRH tended to be significantly higher in the patients compared to controls (Table 1). These preliminary findings suggest a subtle hypocortisolism and inferred central CRH deficiency in patients with idiopathic hypersomnia. A central CRH deficiency in these patients is consistent with

their clinical profile of increased daytime sleepiness and deep nocturnal sleep (generalized hypoarousal).

The stress related cytokines (TNF- α , IL-1, and IL-6) have been suggested as potential mediators of excessive daytime sleepiness (Table 1). In 1997, a report on the morning plasma levels of TNF- α , IL-1 β , and IL-6 in patients with sleep apnea, narcolepsy and idiopathic hypersomnia showed that TNF- α was significantly elevated in people with sleep apnea and narcolepsy compared to that in normal controls. Plasma IL-1 β concentrations were not different between the sleep disorder patients and controls, whereas IL-6 was markedly and significantly elevated in patients with sleep apnea compared to that in normal controls. The primary factor in the elevation of plasma TNF- α values was the degree of nocturnal sleep disturbance, whereas the primary determinant for IL-6 levels was body mass index. These findings suggest that TNF- α and IL-6 might play a significant role in mediating sleepiness and fatigue in disorders of excessive daytime sleepiness in humans. Also, it was hypothesized that IL-6 plays a role in mediating sleepiness in obese patients, even those without obstructive sleep apnea, who experience, as confirmed also in the sleep laboratory, a significant degree of daytime sleepiness and fatigue. In 1996, another study reported that the circadian rhythm of TNF- α was significantly altered in patients with sleep apnea and that the peak concentration that occurred during the night in normal control subjects was not present in patients. Rather, the patients exhibited increased TNF- α concentrations in the afternoon, the time period during which concentrations in normal control subjects were at a minimum. Furthermore, in this study, it was reported that the alteration in the cytokine profiles were not normalized by the CPAP therapy. Since then, several studies have confirmed that TNF- α and IL-6 are elevated in disorders of excessive daytime sleepiness, i.e., sleep apnea and narcolepsy independently of confounding variables such as obesity. Interestingly, a recent study reported that neutralizing TNF- α is associated with a significant decrease of sleepiness in patients with sleep apnea.

Conclusion

In conclusion, the collective findings on the association between sleep and stress system appear to suggest that sleep is a major antistress mechanism that is vital in the preservation of the physical and mental homeostasis of the human species. Also, sleep loss appears to be a physical and mental stress to humans, whereas sleep disorders/disturbances may lead to a significant dysregulation of the stress system. More knowledge

on the association between sleep, sleep disorders, and stress system would lead to a better understanding of the mechanisms that underlie sleep's capacities for physical and mental restoration and to improve treatment of sleep disorders/disturbances.

Summary

Glossary

<i>Acetylcholine</i>	A neurotransmitter in the brain that has receptors on nerve cells that nicotine stimulates and promotes the firing of.
<i>Affect</i>	Moods, emotions, and feelings, including negative affect (e.g., anxiety, depressive mood, and anger) and positive affect (e.g., euphoria, vigor, and pleasant feelings).
<i>Cognitive dysfunction</i>	The impairment or biasing of information processes such as perceptual, attentional, and memorial functions that can be caused by temporary physiological and mood states, as well as by longer-lasting forms of psychopathology, neurological abnormality, or temperamental bias.
<i>Dopamine</i>	A neurotransmitter in the brain having a number of functions, including the enhancement of attention and signaling of reward in response to appetitive stimuli.
<i>Neuro-transmitter</i>	A chemical released at the synapse (junction) between nerves that promotes the conduction of nerves impulses from one nerve to another.
<i>Nicotine</i>	The primary psychoactive component of tobacco smoke; it binds to endogenous nicotinic acetylcholine receptors, which results in a variety of neuronal actions.

Introduction

Smoking remains the number one preventable cause of death and disability in the United States and is a burden on people, economies, and health-care systems worldwide. Knowledge about the relation of smoking and stress has expanded exponentially in the last 3 decades as a result of new findings in the fields of genetics, neuroscience, and clinical research. This research has revolutionized thinking about who smokes and why it is so difficult for many to quit. Genes have been found to play a significant role in determining who becomes and remains a smoker. Some of the genes that predispose some people to smoke predispose the same individuals to experience higher than normal levels of stress and negative mood states. These and related findings indicate that there are many clinically and theoretically important relations among smoking, stress, and coping.

Personality Traits, Genetic, and Biological Predictors of Smoking and Stress

Evidence shows clear and substantial relations among smoking, stress-related personality traits, and psychopathology. Further, all these characteristics are largely heritable (passed on from generation to generation via genes) and share common genetic bases.

Stress, Personality, Psychopathology, and Smoking

Individuals with specific psychiatric problems and personality traits leading to frequent or intense personal distress are substantially more likely to smoke. Smoking rates are disproportionately high in individuals with psychiatric conditions, including major depressive disorder, various anxiety disorders, schizophrenia,

antisocial personality disorder, attention deficit hyperactivity disorder (ADHD), and various substance abuse disorders, including alcoholism. The prevalence of smoking in individuals with a lifetime history of these conditions is two to three times higher than in unaffected individuals. The personality traits associated with the increased prevalence of smoking reflect dispositions that are similar in nature to psychiatric disorders. For example, the personality trait of neuroticism (the general tendency to experience negative affect and stress) has been found to be associated with higher prevalence of smoking. Smoking (and drug abuse more broadly) is also much more prevalent among individuals high in impulsiveness or sensation-seeking traits. In addition to finding relations between these traits and smoking among adults, longitudinal studies have shown that children and adolescents with these traits are more likely to smoke as adults (as well as to use other drugs). Taken together, these data suggest that smoking behavior is not randomly distributed in the adult population and also support the notion that nicotine plays some role in the psychological life of the smoker beyond simple addiction or withdrawal alleviation.

Identical Genes Related to Smoking, Psychopathology, and Personality Traits

Results from family, twin, and molecular genetic studies demonstrate that genetic factors play an important role in smoking behavior and stress responses. Genes account for approximately half of the variability in who will smoke and who will not. Further, many of the same genes that predispose individuals to smoke are also responsible, in part, for predisposing individuals to the stress-related personality traits and psychiatric disorders previously mentioned. For instance, the same genes that contribute to a vulnerability to neuroticism also appear to dispose individuals to clinical depression and to smoking. Similarly, the same genes that contribute to impulsivity and sensation seeking also contribute to a variety of compulsive behaviors, including drug abuse, antisocial behavior, and smoking.

The identification of some of the many genes that contribute to smoking and smoking-related traits has been one of the major accomplishments of recent years. Genetically influenced biological differences between people in (1) brain neurotransmitter receptors and (2) liver enzymes related to nicotine metabolism appear to play roles in determining smoking. Some of the most exciting insights in this area are related to the neurotransmitter dopamine. Dopamine is intimately associated with coping, stress, natural reward, and the pleasurable effects of abused drugs, including nicotine. A number of genes combine to

determine a person's brain dopamine system functioning. Those individuals with low dopaminergic system functioning levels are more likely than others to smoke, abuse alcohol and other drugs, and have impulsive and sensation-seeking personality traits. Thus, these dopamine genes appear to contribute to the association of smoking with these personality traits and substance-abuse patterns.

Smoking as a Coping Response

These personality traits and psychiatric conditions are associated with distressing cognitive and emotional states. To the degree smoking is effective at ameliorating these undesirable cognitive or affective states, coping by means of smoking will occur and will be experienced as rewarding by a smoker. It is not surprising, then, that those individuals who frequently experience cognitive and affective states that can be improved by smoking are more likely than others to find smoking to be a useful and reinforcing tool (and thus smoke more often).

Although smokers as a group report smoking to reduce negative affect; cope with stress; reduce weight or appetite; and enhance stimulation, cognitive performance, and pleasure, the relative importance of these smoking motivations vary across (and also within) smokers. Consistent with the coping model, those who are depression prone are more likely to say they smoke to reduce depressive moods and thoughts, whereas those with attentional problems say they smoke more often to enhance attention and, in turn, those who are prone to anxiety are more likely to say they smoke to alleviate anxiety. Similarly, individuals who are motivated to keep from gaining weight value the fact that smoking helps maintain a lower body weight. Thus, the motivations to smoke are to some extent consistent with personality traits of the smokers. This tendency to smoke for reasons related to personality traits is called trait-adaptive responding because smoking reflects an adaptive coping response related to the smoker's specific personality traits (see [Figure 1](#)).

Smoking/Nicotine as a Coping Response

Withdrawal alleviation As previously suggested, one theory proposes that smoking alleviates stress only to the extent that nicotine withdrawal is stressful to smokers. These withdrawal alleviation theories are supported by the simple fact that smokers find abstinence from smoking stressful and smoking alleviates this stress. A related theory suggests that smokers so come to associate withdrawal-induced stress with negative states that any negative state – whether during withdrawal or not – cues smoking behavior.

Figure 1 Biologically based traits increase the frequency and severity of trait-consistent states. To the extent that these states are improved by smoking/nicotine, smoking is reinforced.

Although withdrawal alleviation models of smoking and stress are compelling, they cannot provide a complete picture of nicotine dependence. The withdrawal alleviation model suggests the stress of withdrawal is temporary; once withdrawal subsides the now-ex-smokers will return to their presmoking affective and cognitive states. Indeed, many studies have reported temporary increases in negative affect, stress, and difficulty concentrating following quitting that return to or improve beyond prequit levels in a matter of weeks. However, these studies have been limited by a number of factors that might preclude accurate characterization of withdrawal in smokers. First, because these studies do not take into account data of smokers who relapse (i.e., smokers for whom quitting is most difficult), the findings minimize the negative affect and distress the majority of smokers experience on quitting. Second, these studies have often not included a continuing-to-smoke control group, so other factors affecting mood and cognition, such as the passage of time, are also not accounted for.

When these two limitations are eliminated from research designs, a different picture of withdrawal emerges. Recent longitudinal studies that minimize relapse and include adequate control groups have observed transient increases in negative affect, stress, and difficulty concentrating that do not return to baseline levels, or the approximate levels of these symptoms in a continuing-to-smoke control group. These findings suggest that smokers may smoke, in part, to reduce underlying distressful cognitive and affective states that were present prior to becoming a

smoker, which, on quitting smoking, are rerevealed. Thus, smokers may smoke in order to alleviate withdrawal symptoms to a degree, but also smoke in order to self-medicate underlying trait-based problems. It should be noted, however, that well-designed studies to date have accurately assessed the effects of quitting smoking on negative affect for only 45 days of abstinence. Thus, it is possible that after a longer period of time effects of quitting do resolve in most quitters.

Absolute inherent effects nicotine A growing body of research suggests that nicotine can, under specific situations, improve mood and cognitive performance, even in smokers who are only minimally deprived of nicotine or in nonsmokers. Laboratory studies show that smoking and other forms of nicotine delivery usually reduce negative moods and emotions in situations in which stressors are ambiguous and/or not dominant, such as situations in which an individual is anticipating experiencing stress. In contrast, when the context includes clear, immediate, and potent threat stimuli, negative moods are not impacted by smoking or nicotine.

Many experts and some experimental evidence suggest that nicotine can also indirectly promote positive affect and minimize negative affect in situations in which nicotine contributes to goal achievement. For example, when they need to concentrate for a long period of time to accomplish a goal, such as writing a paper, smokers say they smoke to sustain their concentration and thereby achieve their goal. Laboratory studies have also shown nicotine to facilitate cognitive functions, including vigilance and memory,

in both habitual tobacco users and in individuals with no prior exposure to nicotine. In addition, other studies have shown that nicotine may improve affect and reduce stress by helping smokers focus on emotionally positive or neutral distractors. Research suggests that nicotine is especially effective at reducing stress when there is a substantial degree of choice as to whether or not to attend to stressful cues and when some of these nonstressful cues are emotionally positive.

A two-factor model of smoking A combined two-factor model proposes that smokers smoke in order to (1) prevent or alleviate withdrawal and (2) gain beneficial effects inherent in nicotine. Among heavy smokers, the acute effects of abstinence resolve across the first week or two of abstinence; thereafter, underlying psychological and pathological traits are rerevealed and greater stress, negative affect, and difficulty concentrating are experienced. Similarly, the attention and mood-enhancing effects of most habitually used stimulant drugs (caffeine, amphetamine, and cocaine) appear to reflect the combined influence of such inherent and withdrawal-alleviation mechanisms.

Habit, sensory aspects, and other factors Smokers may smoke for numerous reasons other than those already described. Many smokers find the sensory aspects of smoking pleasurable (e.g., the feel of smoke in lungs and the taste), and these sensory cues further reinforce smoking behavior. Further, many smokers, regardless of why they started smoking in the first place, may continue to smoke, largely out of habit. Finally, recent evidence suggests that nonnicotine chemicals in tobacco smoke may have anti-depressant qualities that may further ameliorate negative affect and reinforce smoking behavior.

Smoking Cessation, Stress, and Coping

Based on the empirical evidence showing that smoking cessation is frequently a stressful process resulting in more coping failures than successes, clinicians and researchers have spent much time and energy on minimizing smoking-cessation-related stress and maximizing coping.

Psychological and Behavioral Therapies for Smoking Cessation

Most of the widely used smoking cessation programs include several hours of skills training in cognitive and behavioral techniques designed to help the smoker cope not only with the cravings to smoke but also

with negative mood states frequently associated with quitting and known to promote relapse to smoking. Such techniques include behavioral relaxation training and learning to think about stressful situations in a manner that is less likely to produce negative emotional states. Currently popular pharmacological treatments, such as nicotine gum, nicotine patches, and the antidepressant drug Zyban, also include a complex therapeutic package that includes behavioral relaxation and coping components, along with information about the cessation process and social support.

Antidepressant Medication Therapies for Smoking Cessation

Consistent with the view that smoking motivation and the effects of smoking cessation are mediated by brain mechanisms related to negative affect and depression, one antidepressant medication, Zyban, has been found to be beneficial in helping individuals maintain smoking abstinence. This U.S. Food and Drug Administration (FDA)-approved smoking-cessation drug is also marketed under a different brand name as an antidepressant medication.

The Psychobiology of Smoking, Coping, and Stress Diasthesis

During withdrawal from nicotine, smokers with depressive tendencies have been found to exhibit brain wave (via electroencephalogram, EEG) asymmetry profiles characteristic of depressed individuals. These abstinence-induced EEG asymmetries appear to last for at least a month after quitting. The EEG asymmetry seen in these individuals is a relatively greater EEG slowing of the left (compared to the right) frontal cortex subsequent to quitting. Left-hemisphere processing is associated with active coping, verbal behavior, and positive affect, whereas right-hemisphere processing is more associated with negative mood states and withdrawal. These and related findings suggest that nicotine may act as an antidepressant in part because in individuals prone to depression it tends to increase the activation more in the left than in the right frontal cortex. Overall, nicotine tends to increase brain activation as measured by EEG, whereas smoking abstinence tends to decrease EEG activity in both hemispheres, although to a greater extent in the left relative than in the right frontal cortex. This decrease in EEG activation corresponds to the sustained decrease in ability to concentrate also found to last for at least a month after quitting smoking.

The EEG-activating effects of smoking are thought to reflect the effects of nicotine on brain receptors for the neurotransmitter acetylcholine. Nicotine has the ability to stimulate cholinergic receptors throughout the body. The stimulation of these cholinergic receptors can result in a cascade of events, including increases in heart rate, blood pressure, blood cortisol concentrations and the activation of other neurotransmitter systems in the brain. Another important brain system influenced by nicotine uses dopamine as its neurotransmitter. Dopamine (DA) is associated with brain regions involved in attention, emotion, coping, and reward. DA is involved in coping in both positive and negative emotional states. Nicotine-induced increments in brain mesolimbic DA activity may increase the ability of the organism to avoid aversive stimuli and to obtain positive ones.

The effects of smoking on EEG, mood, and attention discussed so far have been found to be due primarily to the effects of nicotine; however, recent evidence suggests that an unidentified component of tobacco smoke (other than nicotine) inhibits monoamine oxidase (MAO) activity in the brain in the same manner as some antidepressant medications. Thus, it may be that some of smoking's antidepressant, mood-enhancing, and cognitive benefits come from the inhibition of MAO activity by something other than nicotine.

Summary

Environment, genetics, personality, and psychopathologic traits interact to determine smoker status and the type of smoker an individual becomes. Individuals genetically and otherwise predisposed to negative affect, sensation seeking, and/or suboptimal cognitive performance are more likely to be exposed to smoking environments, start smoking in order to seek negative affect relief or as an act of sensation seeking, and find smoking reinforcing. The widely held belief among smokers and nonsmokers that smoking reduces negative affect and enhances cognition leads predisposed individuals to experiment with smoking as a form of self-medication, to minimize negative affect, and to maximize cognitive functioning. The affect-modulating and cognitive-enhancing effects of nicotine are more reinforcing to those who need and value them the most – those in stressful circumstances and those with a vulnerability to cognitive and affective dysfunction. When individuals who are predisposed to smoking try to quit, they lose the beneficial effects of nicotine and are especially vulnerable to experiencing the cognitive or affective state to which they are predisposed. Thus, depression-prone

individuals are more likely to become depressed, anxiety-prone individuals are more prone to anxiety, and attentionally disordered quitters are disposed to suffer more severe attention problems. The enhanced severity of cognitive and affective responses to quitting contributes to the failure of vulnerable individuals to maintain abstinence after efforts to quit smoking. Smoking in individuals who are vulnerable to smoking can thus be seen as an attempt to adapt to their situation by altering their cognitive and/or affective state.

However, affective and cognitive traits also alter the probability of smoking by more indirect mechanisms. Both affective and cognitive traits influence long-term goals by a number of indirect mechanisms. For example, risk-taking and other reward and sensation-seeking behaviors make certain individuals temperamentally insensitive to cues of potential punishment (e.g., health warnings about smoking) and promote cognitive, social, and behavioral sequences that reinforce smoking and other risk-taking behavior. The sensation-seeking life style, which includes smoking, drinking, and a focus on pleasure, may be so reinforcing to individuals with a strong genetic disposition that their cognitive motivational schemas include no plans to quit any risky behaviors. In contrast, negative-affect-prone individuals are likely to focus on the immediate relief of negative affect produced by smoking rather than on the long-term health consequences. Individuals who are more psychobiologically stable will see less benefit from smoking and be less inclined to take up or continue smoking because the perceived risks outweigh the perceived gains.

Negative Effects of Social Capital

Glossary

<i>Bonding social capital</i>	Social connections that exist within homogeneous groups, for example the strong ties that connect family members, close friends, or neighbors who are alike with respect to race/ethnicity, social class, and religion.
<i>Bridging social capital</i>	Social connections that cross race/ethnic, class, and other boundaries.
<i>Social capital</i>	The resources available to individuals and groups through their social connections and membership in community networks.

Forms and Functions of Social Capital

Social capital is the resources available to individuals through their social connections and membership in community networks. In contrast to financial capital, which resides in people's bank accounts, or human capital, which is embodied in individuals' investments in education and job training, social capital inheres in the structure and quality of social relationships between individuals.

The concept was originally developed in sociology and political science. According to James Coleman, social capital can take on several different forms, such as levels of trust within a social structure, norms and sanctions, information channels, and appropriable social organizations. An example of an appropriable social organization is the case of a residents' association in an urban housing project that formed initially for the purpose of pressuring builders to fix various problems (e.g., leaks and crumbling sidewalks). After the original problems were solved, the organization remained as available social capital within the community to improve the quality of life of residents in other ways.

In fields outside of health, social capital has been applied in a variety of settings ranging from the smooth and effective functioning of government institutions to the ability of communities to solve the

problems of collective action, such as intervening to prevent the occurrence of juvenile delinquency. More recently, empirical studies have begun to link social capital to population health outcomes.

Measurement of Social Capital

Two approaches have been used to measure social capital: (1) surveys and (2) direct social observations. In the survey-based approach, researchers inquired about a range of attitudes (trust of others and expectations of reciprocity and mutual aid) as well as behaviors (e.g., membership in community organizations, levels of voluntarism, and intensity of informal social interactions with neighbors) that are thought to be indicative of social capital. By contrast, direct social observation may involve the use of experimental methods, such as the letter-drop experiment in which stamped addressed envelopes are deliberately dropped on street corners to determine the proportion of letters that are subsequently mailed to the addressee by strangers (an experimental indicator of reciprocity). More commonly, direct observational approaches emphasize the observable characteristics of communities that may serve as proxies for the extent of social capital, such as the density of voluntary associations within a given locality.

Given the well-established tradition in community psychology of studying the characteristics of cohesive communities, there is legitimate debate over the extent to which the concept of social capital represents old wine in new bottles. In community psychology, concepts such as the psychological sense of community, community competence, and neighboring all predate the current vogue for the term social capital. In addition, there is an extensive prior literature in health psychology and social epidemiology on the related constructs of social support and social integration. However, an important distinction between social support and social capital is that, whereas the former variable is measured at the individual level, the latter is most often conceptualized and measured at the community or area level. That is, social capital has most often been considered to be a property of the collective (neighborhoods, cities, or even regions).

If social capital is indeed a collective property, a critical question is whether aggregated responses to social surveys (e.g., in response to questions about trusting neighbors) genuinely represent a group characteristic or whether they are confounded by other characteristics of the individual respondents that correlate with perceptions of social capital. Some evidence suggests that aggregated survey responses actually capture genuine place-based differences. An analysis of the Community Survey of the Project

on Human Development in Chicago Neighborhoods reported that even after controlling for the socio-demographic attributes of individual respondents (age, sex, race/ethnic status, income, and schooling), there were significant between-neighborhood variations in levels of social capital as measured by perceptions of trust.

Finally, research has increasingly pointed out the important distinction between bonding and bridging social capital. Bonding social capital refers to the social connections that exist within homogeneous groups, for example the strong ties that connect family members, close friends, or neighbors who are alike with respect to race/ethnicity, social class, and religion. By contrast, bridging social capital refers to social connections that cross race/ethnic, class, and other boundaries.

Social Capital and Population Health

Empirical studies have linked social capital to a growing number of population health outcomes, including mortality, mental health, health-related behaviors, self-rated health, and disability. In one of the first ecological analyses, indicators of social capital at the U.S. state level (levels of trust, perceptions of reciprocity, and density of civic associations) were strongly correlated with all-cause and cause-specific mortality rates. Subsequent investigations extended these findings down to the neighborhood level. In a study based in the 343 neighborhoods of Chicago, the levels of trust, reciprocity, and group membership were found to be significantly inversely correlated with mortality rates for residents, even after controlling for the degree of economic deprivation.

Increasingly, studies of social capital and health have used multilevel analysis, with interesting results. In one study of mental health among African American residents of a disadvantaged community in Alabama, higher bonding social capital was found to be associated with worse mental health outcomes, whereas bridging social capital was found to be associated with better mental health. In other words, within the context of a highly disadvantaged community, a greater level of social connection and involvement may be associated with worse health outcomes because of the strains associated with the obligation to help others in such settings. In another study analyzing self-rated health within the 2000 Social Capital Community Benchmark Survey (conducted in 40 U.S. communities), a complex interaction was found between community levels of social trust and individual levels of trust. Among individuals who expressed a high level of trust of others, there was a positive influence (on self-rated health) of living in

communities with higher levels of trust. On the other hand, the opposite was found for individuals expressing mistrust of others in their community. For these individuals, the higher the community's level of trust, the worse they felt.

Mechanisms Linking Social Capital and Health

Several mechanisms have been hypothesized through which social capital can influence health. They include:

1. The ability of a community to undertake collective action (e.g., organizing to pass local ordinances that restrict smoking in public places or lobbying to fight the closure of local clinics).
2. The ability of a community to enforce healthy norms by exercising informal social control over deviant behaviors (e.g., underage drinking, smoking, and drug abuse).
3. The faster diffusion of innovation through information channels (e.g., new knowledge about a new cancer screening test).
4. The exchange of social support between members of the community (e.g., the provisions of emotional support and stress-buffering or the exchange of instrumental aid, such as cash loans, during emergencies).

It is important to emphasize, however, that not all kinds of social capital result in beneficial outcomes for health. Like any form of capital (e.g., financial capital), social capital can be used for pro-social as well as antisocial ends and can result in deleterious as well as beneficial health outcomes.

Negative Effects of Social Capital

Social capital is not a panacea for health promotion. Strong social ties within a group or a community (high bonding social capital) can imply a high level of social exchange, which in turn translates into role strain for certain members of the in-group (the support providers, who are often women). Strong bonding social capital can often coexist with conflict between the group and outside social groups (low bridging social capital). In some instances, high social capital within a community has been channeled to

exclude outsiders from entering the community – for example, by enforcing residential segregation. Strong levels of social cohesion can also imply restrictions on the freedom of individual expression as well as a downleveling of achievement norms. In addition, some forms of social capital, such as criminal gangs, may provide benefits to its members, but do very little to foster social cohesion with the rest of society. Finally, some have criticized the concept of social capital for encouraging the blaming of victims (or, in this case, the blaming of communities) for their problems. These criticisms emphasize the caution warranted in applying the concept of social capital in health promotion.

Theoretical Orientations

Health, Social Networks, and Social Integration

A Conceptual Model Linking Social Networks to Health

Conclusion

Glossary

<i>Appraisal support</i>	Help in decision making, giving appropriate feedback, or help deciding which course of action to take.
<i>Emotional support</i>	The amount of loving and caring, sympathy and understanding, and/or esteem and value available from others.
<i>Instrumental support</i>	Help, aid, or assistance with tangible needs such as getting groceries, getting to appointments, and cooking; aid in kind, money, or labor.
<i>Social networks</i>	The web of social relationships that surrounds an individual and the characteristics of those ties.
<i>Social participation and engagement</i>	The enactment or interaction of social ties in real-life activity. Meeting with friends and family, attending social or religious functions, and participating in occupational or social roles or in group recreation are examples.

Introduction

Over the last 25 years, there have been dozens of articles and books on issues related to social networks and social support. It is now widely recognized that social relationships and affiliation have powerful effects on physical and mental health for a number of reasons.

When investigators write about the impact of social relationships on health, many terms are used loosely and interchangeably, including social networks, social support, social ties and social integration. The aim of this article is to (1) discuss theoretical orientations from diverse disciplines that we believe are fundamental to advancing research in this area, (2) briefly review findings related to mortality and biological pathways leading to poor health, (3) provide a set of definitions of networks and aspects of networks and

support, and (4) present an overarching model that integrates multilevel phenomena.

Theoretical Orientations

There are several sets of theories that form the bedrock for the empirical investigation of social relationships and their influence on health. The earliest theories came from sociologists such as Emile Durkheim, as well as from psychoanalysts such as John Bowlby, who first formulated attachment theory. A major wave of conceptual development also came from anthropologists, including Bott, Barnes, and Mitchell, and from quantitative sociologists, such as Fischer, Laumann, Wellman, and Marsden, who, along with others, developed social network analysis. This eclectic mix of theoretical approaches coupled with the contributions of epidemiologists form the foundation of research on social ties and health.

Durkheim's contribution to the study of the relationship between society and health is immeasurable. Perhaps most important is his contribution to the understanding of how social integration and cohesion influence suicide. Durkheim's primary aim was to explain how individual pathology was a function of social dynamics. In light of recent attention to upstream determinants of health, Durkheim's work reemerges with great relevance today.

Social Network Theory: A New Way of Looking at Social Structure and Community

During the mid-1950s, a number of British anthropologists found it increasingly difficult to understand the behavior of either individuals or groups on the basis of traditional categories such as kin groups, tribes, or villages. Barnes and Bott developed the concept social networks to analyze ties that cut across traditional kinship, residential, and class groups and to explain behaviors they observed such as access to jobs, political activity, and marital roles. The development of social network models provided a way to view the structural properties of relationships among people.

Network analysis "focuses on the characteristic patterns of ties between actors in a social system rather than on characteristics of the individual actors themselves and use these descriptions to study how these social structures constrain network member's behavior" (Hall and Wellman, 1985: 26). Network analysis focuses on the structure and composition of

the network and on the contents or specific resources that flow through those networks. The strength of social network theory rests on the testable assumption that the social structure of the network itself is largely responsible for determining individual behavior and attitudes by shaping the flow of resources that determine access to opportunities and constraints on behavior.

Health, Social Networks, and Social Integration

From the mid-1970s to the present, there have been a series of studies consistently showing that the lack of social ties or social networks predicts mortality from almost every cause of death. There are now a number of studies, relating outcomes to morbidity and biomarkers of stress or resilience to inflammation, metabolic and neuroendocrine functioning, and cardiovascular reactivity, that also support the hypothesis that social networks impact health and well-being directly through multiple pathophysiological mechanisms. Social networks and support may both directly affect health outcomes and buffer the effects of other stressful experiences.

Here, we briefly review the mortality studies. In the first of these studies from Alameda County, men and women who lacked ties to others (in this case, based on an index assessing contacts with friends and relatives, marital status, and church and group membership) were 1.9–3.1 times more likely to die in a 9-year follow-up period than those who had many more contacts. Another study, in Tecumseh, Michigan, showed a similar strength of positive association for men, but not for women, between social connectedness/social participation and mortality risk over a 10–12 year period; this study has the additional strength that it controlled for some biomedical predictors assessed from physical examination (e.g., cholesterol, blood pressure, and respiratory function).

Similar results have been reported from several studies in the United States and from three in Scandinavia. Investigators working on a study in Evans County, Georgia, found risks to be significant in older White men and women without social networks, even when biomedical and sociodemographic risk factors were controlled for, although some racial and gender differences were observed. Two studies in Sweden reported significantly increased risks among socially isolated adults, and a study of men and women in eastern Finland found that social connections were related to mortality risk for men, but not for women, independently of standard cardiovascular risk factors.

Studies of older men and women confirm the continued importance of these relationships into late life. Furthermore, two studies of large cohorts of men and women in a large health maintenance organization and 32,000 male health professionals suggested that social networks are, in general, more strongly related to mortality than to the incidence or onset of disease.

Two more recent studies in Danish men and in Japanese men and women further indicated that aspects of social isolation or social support are related to mortality. Virtually all these studies found that people who are socially isolated or disconnected from others are between two and five times more likely to die from all causes, compared to those who maintain strong ties to friends, family, and community.

Social networks and support have been found to predict a very broad array of other health outcomes from survival post-myocardial infarction to disease progression, functioning, and the onset and course of infectious diseases. Several studies suggested that social isolation is related to C-reactive protein (especially in men), measures of allostatic load, fibrinogen and cardiovascular reactivity, and neuroendocrine function. Although observational studies have been reasonably consistent in linking social isolation to outcome, psychosocial interventions have not been as successful at producing changes in social isolation or support that translate into better health outcomes.

A Conceptual Model Linking Social Networks to Health

Although the power of using measures of networks or social integration to predict health outcomes is indisputable, the interpretation of what the measures actually measure has been open to much debate. Hall and Wellman have appropriately commented that much of the work in social epidemiology has used the term social networks metaphorically because rarely have investigators conformed to more standard assessments used in network analysis. This criticism has been duly noted, and several calls have gone out to develop a second generation of network measures.

A second wave of research developed in reaction to this early work and as an outgrowth of work in health psychology, which has turned the orientation of the field in several ways. These social scientists focused on the qualitative aspects of social relations (i.e., their provision of social support or, conversely, the detrimental aspects of relationships) rather than on the elaboration of the structural aspects of social networks. Most of these investigators followed the assumption that what is most important about networks is the support functions they provide. Although

social support is among the primary pathways by which social networks may influence physical and mental health status, it is not the only critical pathway. Moreover, the exclusive study of more proximal pathways detracts from the need to focus on the social context and structural underpinnings that may significantly influence the types and extent of social support provided.

In order to have a comprehensive framework in which to explain these phenomena, it is helpful to move upstream and return to a more Durkheimian orientation to network structure and social context. It is critical to maintain a view of social networks as lodged within those larger social and cultural contexts that shape the structure of networks.

Conceptually, social networks are embedded in a macro-social environment in which large-scale social forces may influence network structure, which in turn influences a cascading causal process beginning with the macro-social to psychobiological processes to impact health. In this framework, social networks are embedded in a larger social and cultural context in which upstream forces are seen to condition network structure.

Networks may operate at the behavioral level through at least five primary pathways: (1) provision of social support, (2) social influence, (3) social engagement and attachment, (4) person-to-person contact, and (5) access to resources and material goods. These psychosocial and behavioral processes may influence even more proximate pathways to health status, including direct physiological responses; psychological states, including self-esteem, self-efficacy, and depression; health-damaging behaviors such as tobacco consumption or high-risk sexual activity, health-promoting behavior such as appropriate health service use and exercise, and exposure to infectious disease agents such as human immunodeficiency virus (HIV), other sexually transmitted diseases (STDs), and tuberculosis.

The Assessment of Social Networks

Social networks might be defined as the web of social relationships that surround an individual and the characteristics of those ties. Network characteristics are:

- Range or size: the number of network members.
- Density: the extent to which the members are connected to each other.
- Boundedness: the degree to which they are defined on the basis of traditional structures such as kin, work, and neighborhood.
- Homogeneity: the extent to which individuals are similar to each other in a network.

Related to network structure, the characteristics of individual ties include:

- Frequency of contact.
- Multiplexity: the number of types of transactions or support flowing through ties.
- Duration: the length of time an individual knows another
- Reciprocity: the extent to which exchanges are reciprocal.

Downstream Social and Behavioral Pathways

We next briefly review the primary pathways by which networks may influence health.

Social support Moving downstream, we now consider the mediating pathways by which networks might influence health status. Most obviously, the structure of network ties influences health via the provision of many kinds of support. This framework immediately acknowledges that not all ties are supportive and that there is variation in the type, frequency, intensity, and extent of support provided. For example, some ties provide several types of support, whereas other ties are specialized and provide only one type. Social support is typically divided into emotional, instrumental, appraisal, and informational support.

Emotional support is related to the amount of “love and caring, sympathy and understanding and/or esteem or value available from others” (Thoits 1995: 64). Emotional support is most often provided by a confidant or intimate other, although less intimate ties can provide such support under circumscribed conditions. Instrumental support refers to help, aid, or assistance with tangible needs such as getting groceries, getting to appointments, phoning, cooking, cleaning, and paying bills. House identifies instrumental support as aid in kind, money, or labor. Appraisal support is help in decision making, help by giving appropriate feedback, or help in deciding which course of action to take. Informational support is the provision of advice or information in the service of particular needs. Emotional, appraisal, and informational support are often difficult to disaggregate and have various other definitions (e.g., self-esteem support).

Perhaps even deeper than support are the ways in which social relationships provide a basis for intimacy and attachment. Intimacy and attachment have meaning not only for relationships that we traditionally think of as intimate (e.g., between partners and between parents and children) but also for more extended ties. For instance, when relationships are

solid at a community level, individuals feel strong bonds and attachment to places (e.g., neighborhood) and organizations (e.g., voluntary and religious).

Social influence Networks may influence health via several other pathways. One pathway increasingly recognized is social influence. Shared norms around health behaviors (e.g., alcohol and cigarette consumption, sexual practices, and health-care use) might be powerful sources of social influence with direct consequences for the behaviors of network members. For instance, the relationships of adolescent girls with both their male and female friends and with their parents are associated with pregnancy risk. The social influence that extends from the network's values and norms constitutes an important and underappreciated pathway through which networks impact health.

Social engagement and attachment A third and more difficult-to-define pathway by which networks may influence health status is by promoting social participation and social engagement. Participation and engagement result from the enactment of potential ties in real-life activity. Getting together with friends, attending social functions, participating in occupational or social roles, joining in group recreation, attending church are all instances of social engagement. Thus, through opportunities for engagement, social networks define and reinforce meaningful social roles, including parental, familial, occupational, and community roles, which in turn provide a sense of value, belonging, and attachment. Several recent studies suggest that social engagement is critical in maintaining cognitive ability and in reducing mortality.

In addition, network participation provides opportunities for companionship and sociability. Some have argued that these behaviors and attitudes are not the result of the provision of support *per se* but are the consequence of participation in a meaningful social context in and of itself. One reason measures of social integration or connectedness may be such powerful predictors of mortality over long periods of follow-up is that these ties give meaning to individuals' lives by virtue of enabling them to participate fully, to be obligated (in fact, often to be the providers of support), and to feel attached to their community.

Person-to-person contact Another behavioral pathway by which networks influence disease is by restricting or promoting exposure to infectious disease agents. In this regard, the methodological links between epidemiology and networks are striking. What is perhaps most remarkable is that the same network characteristics that can be health-promoting

can at the same time be health-damaging if they serve as vectors for the spread of infectious disease. Efforts to link mathematical models applying network approaches to epidemiology are in their infancy and have started to appear over the last 10 years.

The contribution of social network analysis to model of disease transmission is the understanding that in many, if not most cases, disease transmission is not spread randomly throughout a population. Social network analysis is well suited to the development of models in which exposure between individuals is not random but rather is based on geographic location, sociodemographic characteristics (e.g., age, race, and gender), or other important characteristics of the individual such as socioeconomic position, occupation, and sexual orientation. Furthermore, because social network analysis focuses on characteristics of the network rather than on characteristics of the individual, it is ideally suited to the study of the diffusion of transmissible diseases through populations via bridging ties between networks or to uncovering the characteristics of ego-centered networks that promote the spread of disease.

Access to resources and material goods Surprisingly little research has sought to examine differential access to material goods, resources, and services as a mechanism through which social networks might operate. This, in our view, is unfortunate given the work of sociologists showing that social networks operate by regulating an individual's access to life opportunities by virtue of the extent to which networks overlap with other networks. In this way, networks operate to provide access or to restrict opportunities in much the same way as the social status does. Perhaps the most important among studies exploring this tie is Granovetter's classic study of the power of weak ties that, on the one hand, lack intimacy but, on the other hand, facilitate the diffusion of influence and information and provide opportunities for mobility.

Conclusion

This article has reviewed the ways in which social isolation, lack of support, and disengagement may be chronically stressful social experiences and are linked to poor health outcomes. With the development of multilevel framework, we are struck by two issues of profound importance. The first is the upstream question of identifying the conditions that influence the development and structure of social networks. Such questions have been the substantive focus of much of social network research, especially in relationship to urbanization, social stratification,

and culture change. Yet little of this work has been integrated with health issues in a way that might guide us in the development of policies or interventions to improve public health. Recent work relating social cohesion to economic inequality has begun to help us decipher the complex interrelationships between these social experiences. Of particular interest are the ways in which social policies may impact the form and function of social networks. For instance, work/family policies and housing policies may impact network and supportive relationships in important ways, ultimately having a health impact.

The second major issue relates to the downstream question. Many investigators have assumed that networks influence health via social support functions. Our framework makes clear that this is but one pathway linking networks to health outcomes. Furthermore, the work on conflict and stress points out not only that are not all relationships positive in valence but that some of the most powerful impacts on health that social relationships may have are through acts of abuse, violence, and trauma. Fully elucidating these downstream experiences and how they are linked to health and via which biological mechanisms remains a major challenge in the field.

Social Status, Health, and Stress

Indicators of Social Status

Social Status and Exposure to Stressful Conditions

Social Status and Vulnerability to Stressful Conditions

Glossary

<i>Coping resources</i>	The personal (e.g., self-esteem and sense of control) and social (most notably, social support) resources an individual has at his or her disposal to counter the adverse effects of the experience of distress.
<i>Coping strategies</i>	The cognitive and behavioral attempts an individual may employ when faced with the experience of distress.
<i>Exposure</i>	The actual confrontation with stressful situations (events) of chronic stressful conditions.
<i>Social status</i>	Any attribute indicating the social position of an individual in a group or in the society. The most important attribute is socioeconomic status, comprising income, education, and occupation.
<i>Vulnerability</i>	The lack of personal and social coping resources, which increases the risk of a greater adverse impact of stressful conditions.

Social Status, Health, and Stress

The relationship between social status and health is intriguing because it challenges existing models of how a distal variable such as social status might affect health. Research in the past decades focused on explaining the association between low social status, especially low socioeconomic status (SES), and poor health, assuming that the greater distress of living in deprived social and material conditions is an important factor in the strong and consistent association between health and social status. The extensive literature on SES and health provides some indications why the theoretical framework of stress should be considered an interesting candidate in furthering our

understanding of the association between SES and health. First, the linearity of the relationship between SES and health implies better health outcomes as individuals ascend the SES continuum, so that even relatively affluent groups exhibit worse health than their higher SES counterparts. This suggests that factors other than the obvious role of inadequate financial resources or poor living conditions are involved and that SES might also affect psychosocial factors. Identifying these factors may be considered a search for more health-proximal processes so as to bridge the gap between indicators of social status and the associated health outcomes. Second, the analysis of potential measurement artifacts shows that the association between social status and health is robust and is little affected by social selection factors, which would be the case if those who are in poor health were at a higher risk of getting a lower social status. Social selection effects are rare, however, and limited to young children who are unable to attend school as a result of a serious and disabling disease. The absence of social selection effects suggests that the strong association between social status and health is explained by social causation mechanisms – social status affects health instead of the other way around. Particular elements of the stress-coping paradigm offer a framework to study the causal chain between social status at one end of the continuum and health at the other one, particularly those elements that deal with conceptualizing environmental risk for health (exposure to stressors) and individual responses to explain the impact of these stressors (vulnerability to stress).

Indicators of Social Status

Traditionally, most social-epidemiological research has employed the criteria of income, occupation, and education for assessing social status. Less frequently, indicators of material wealth such as car ownership, house ownership, the number of computers in the house, or the number of annual holidays have been used. Interestingly, the sociocultural component of SES expressed in educational attainment appears to have a stronger impact than the more socioeconomic elements of income and occupational status. Recent research indicates that the relationship between income and health varies substantially by level of education. Education improves health, and its effects are larger at low levels of income; education

also reduces the strength of the income–health relationship. The linear gradient relationship between income and health is thus more characteristic of groups with higher levels of education, suggesting that education might improve skills needed to cope effectively with stress. This is shown, for example, in the finding that the mother’s educational status is a better predictor of family stress than both family income or the occupational status of the father.

Recently, it has been argued that it is not the absolute level of SES that is important for understanding its association with health and distress but rather inequality from relative standing. There is suggestive evidence that subjective social status (assessed by a ladder with 10 rungs representing where people stand in society in terms of who are the best off, have the most money, have most education, and have the best jobs) is more strongly linked to health in terms of self-rated health, heart rate, and cortisol habituation to repeated stress than the traditional objective measures of SES (education, income, and occupation). The so-called hierarchy stress perspective argues that the gradient-like association between SES and health reflects social ordering rather than material deprivation *per se*. According to this perspective, higher income leads to less stress, less status anxiety, and more perceived control. These underlying mechanisms are psychological and related to relative rather than absolute material deprivation. Social ordering has effects that are no less substantial than absolute deprivation because relative deprivation leads to worse health both directly through physiological pathways (e.g., cortisol levels) and indirectly through maladaptive coping behaviors (e.g., smoking or alcohol consumption). It is noteworthy that in countries with a high degree of income inequality (e.g., the United States) the SES–health gradient is steeper than in economically more egalitarian European countries. Thus, although SES is a reliable and robust indicator of health, SES as such provides few cues for understanding its relationship with stress. In the words of the social epidemiologists Brown and Harris (1978; p. 10), “It is not that the ‘demographic type’ measures are of no use, it is that they are not enough. What is required is their combination with concepts and measures dealing directly and in detail with the immediate . . . experience of the individual.”

Such an approach is found in social role research, advancing the hypothesis that the lower social status of, for example, the nonemployed affects their sense of meaning and purpose in life and has much less to do with the direct material consequences of their income and employment status. Striking findings in this area have been reported 30 years ago on the

disadvantaged social role of nonemployed married women, who generally reported poorer health than both employed married women and men – although it is not clear to what extent social changes since the 1970s concerning the role of women make those observations still valid. These studies revealed that women who confront the double role of parent and employee reported lower levels of psychological distress than women who are devoted to the role of homemaker. These findings suggest that regardless the actual level of stressful experiences due to overload, the social status of worker is somehow beneficial for the employed women’s health. It should be noted, however, that, although working women may be more protected from distress than nonemployed women, they are still confronted with more distress than employed men.

The results from social role studies are corroborated by findings on particular social groups in our Western community who cannot claim high social status regardless of their income, education, or employment status. Research on the elderly, the unmarried, and nonwhites puts results from social role studies in a somewhat different perspective, suggesting that it is not only the meaning associated with particular roles that accounts for the greater distress of those low in social status but also their ranking order in the social group. Individuals from disadvantaged social groups have been reported to be in poorer health and facing more distress, which may be accounted for by their lower social ranking, although direct tests of this assumption in humans are not available. Animal studies have shown that subordination tends to be associated with a chronically overactive stress response (e.g., higher blood pressure). This pattern is believed to reflect the classic picture of dominance hierarchies as linear pecking orders in which resources are unevenly distributed, inequalities are maintained through aggression and intimidation, and subordinates are subject to the most severe resource limitations, the fewest opportunities for coping, and the greatest physical and social stressors. However, recent studies suggest that the relationship between social rank and patterns of the stress response may be more diverse than has been assumed hitherto. More specifically, it appears that the negative effects of low ranking on stress responses may be attenuated by complex affiliative relationships that may help low-status stressed individuals to cope. It is unknown, however, to what extent these studies on social ranking in animals are directly relevant for humans because humans often belong to multiple hierarchies and tend to value most the one in which they rank highest.

Social Status and Exposure to Stressful Conditions

The common approach to social status and psychological distress suggests that those who are in a disadvantaged social position are confronted with more stressors than their more privileged counterparts, either as a result of exposure to more frequent or more intense negative life events or of living in chronic stressful conditions associated with continuous exposure to daily hassles. Thus, this approach reflects the notion that poorer health associated with lower social status results from social causation, emphasizing the role of structural and material conditions in causing distress. The life event approach to stress dictates that major life events (e.g., divorce or being fired) impose a breach in behavioral routines, cause distress, and therefore require adaptive efforts, eventually exhausting the system. The chronic stress approach takes a somewhat different perspective and states that is the repeated exposure to minor events or daily hassles (e.g., refused services or poor transportation facilities) that ultimately causes wear and tear on the individual.

Life Events

The assumption that people with low social status report more life events than those with higher status is corroborated only weakly by empirical research. Insofar as individuals of lower SES have reported higher numbers of life events, most of these events are directly related to financial problems. There is also a higher report of uncontrollable life events, reflecting to some extent the conditions of poverty and deprivation (e.g., discharge due to becoming obsolete) in individuals with lower social status. Still, even when a higher frequency of life events is reported, this generally fails to account for the higher levels of self-reported distress; no more than 10% of the variance in distress is explained by exposure to life events. Adopting an approach that allows for a contextual evaluation of events shows slightly different results, demonstrating that it is not so much the number of events or even their quality (e.g., uncontrollability) that counts but their potential influence on a number of crucial life areas. Research by social epidemiologists Brown and Harris describing the onset of depression in working-class women clearly demonstrated that these women were confronted with life events that had the potential of generating a chain of other stressful events. The most typical event these women reported involved a teenage pregnancy, which caused these young women to drop out of school and engage in an untimely and unwanted marriage, eventually leaving them divorced, socially isolated,

financially deprived, and without a significant chance of entering the labor market or controlling their future in another way – leaving them in a state of hopelessness that is characteristic of depression. Other studies of lower-class women have demonstrated that the lives of these women are fraught with a large number of network events, meaning that they consider the life events experienced by significant others in their social network as if they concerned them directly, which may further explain the higher levels of distress reported by these women. Nevertheless, it is clear that, although the number of major life events appears to be somewhat higher in those occupying low social status, the higher levels of exposure to major life events are not a sufficient explanation to account for the higher levels of distress.

Daily Hassles and Chronic Stressful Conditions

It appears that it is not so much the incidence of particular major life events that is causing high levels of distress in low-social-status individuals but the continuous confrontation with a large number of repetitive small events that mark living in deprived circumstances. The lower an individual is on the SES continuum, the greater the amount of hassles and the greater the time needed to address the basic tasks of living, including shopping in poorly provided facilities, lack of good transportation, poor access to social and health-care facilities, and refused services. Of course, such difficulties in accomplishing daily routines have their echo in social relations. It is not surprising, therefore, that minor conflicts in relationships in work, marriage, and parenting appear to be more common in low-SES individuals. Still, it is hard to imagine that the experience of minor stress is a simple question of individual exposure. Improving the understanding of how chronic stress affects individuals of lower SES may not so much lie in the study of individual experience of these minor stressors but in identifying the environmental features of low-SES neighborhoods themselves, implying that low SES may have an impact on a community level too. Interestingly, research shows that neighborhood-level indicators predict distress above the effects of individual-level indicators. This suggests that the more proximal environment in which people live may provide important information for identifying the environmental features that cause distress. Those in the lower ends of the social-class distribution disproportionately live in deprived neighborhoods, occupy jobs characterized by high demands and low control, and live in social environments in which they are exposed to violence, conflict, abuse, crowding, and noise. All these environmental features may be considered to increase the experience of distress, although it

remains to be answered how these unhealthy environments get under an individual's skin (Taylor & Repetti, 1997). Adopting a perspective that conceptualizes social status as a proxy to understanding the stressful features of particular environments raises the issue of how situational demands should be distinguished from subjective appraisals of these objective demands. This issue constitutes a classic problem in the cognitive approach to stress formulated by Richard Lazarus and deals with the important question of how demands in the environment are appraised and handled by the individual.

Social Status and Vulnerability to Stressful Conditions

No matter how unhealthy and environment is, not all individuals sharing the same environment are affected by that environment in a similar way, suggesting that factors concerning individual susceptibility to these environmental threats are at work. The approach highlighting a differential vulnerability to stressful conditions may improve our understanding of why individuals of lower social status experience more distress. Vulnerability is reflected in the availability of resources that may be helpful in countering the adverse effects of exposure to stress, including the repertoire of coping strategies, social support, and beliefs about control and competence. Because exposure to environmental threats fails to offer a sufficient explanation for the experience of greater distress in low-SES individuals, it has been hypothesized that the availability of coping resources varies with social status. The question is whether and why lower SES is associated with lower availability of these and other coping resources.

Coping

The employment of adequate cognitive and behavioral coping efforts constitutes one of the most important resources for buffering the adverse effects of psychological distress. Individuals who find constructive ways of coping with stress, such as taking direct action or finding meaning in their experience, are better able to withstand the negative effects of stressful circumstances than individuals who believe their coping resources to be minimal or who believe that the situation is beyond their control and rely on avoidance coping strategies, which in the long run often turn out to compromise their health. Generally, people of low social status are more inclined to adopt avoiding and emotion-focused strategies when they are confronted with stress than are their more advantaged peers. Education level and family income directly relate to the frequency of problem-focused

coping for dealing with financial strain and other hassles, with those of low social status reporting less problem-focused coping. Why low SES promotes generally ineffective coping strategies is unknown, although it has been suggested that the acquisition of coping strategies may to some extent be shaped by the continuous confrontation with few possibilities to control their environment. Although research that directly links social status and coping is rare, it has been shown that individuals of low social status are more sensitive to stress and think of it as unpleasant, disruptive and beyond their control. In contrast, individuals with higher social status appear to be less bothered by distressing events and more often regard it as a challenge to do something about it. It thus seems that the appraisal of potentially upsetting situations as uncontrollable and overwhelming may activate dysfunctional coping patterns. More generally, it seems that low-SES environments reduce individuals' reserve capacity to manage stress, thereby increasing negative emotions and cognitions with subsequent effects for dealing with these stressful conditions themselves.

Social Support

The adverse effect of chronic exposure to stressful environments may be partially offset if an individual has at least one supportive person in his or her neighborhood. Living in low-SES communities may compromise the effective use of social contacts, however. Although the social network of low-SES individuals generally is not smaller than the network of those with better education and higher incomes, the networks of low-SES individuals tend to be more homogeneous, with a large proportion of kin, which may affect the type of support provided and its perceived helpfulness. If an individual is not willing to share particular problems with family members, the possibilities for social support decrease dramatically. The larger proportion of kin in the social networks of low-social-status individuals also has consequences for mutual dependency. Asking for help on one occasion implies some kind of obligation to provide support when a family member asks for it on another occasion. The larger proportion of family in the network also bears costs because it may promote the experience of stress when a family member experiences distress. In addition, the rare prospective research in this area demonstrates that the experience of distress may affect the availability of social support. Studies of economic stressors such as financial hardship or unemployment confirm a pattern in which economic stressors lead to increased marital stress and decreased social support.

Social Distribution of Coping Resources

It is not clear why low-SES individuals are at a disadvantage with regard to the availability of coping resources. Vulnerability is thought to be partly genetically determined and partly acquired during childhood and adolescence by accumulating negative experiences, which may be difficult to compensate for. Lack of financial resources and poor material conditions are, of course, more common in low-SES individuals, but these factors do not appear to be the most important determinants of vulnerability. No evidence is available that limited access to coping resources is a direct result of deficient life conditions. Low self-esteem and low personal control are acquired during repetitive and accumulating negative events causing a negative spiral in which an individual learns to be helpless and hopeless. Low chances of employment or low educational attainment do not by themselves cause vulnerability to distress, but this does not mean that vulnerability does not operate at a social level. Particular resources and coping strategies may be distributed differently among the social classes and also particular beliefs about stress and health may be socially shaped and transmitted. The employment of ineffective coping strategies seems to depend on strong beliefs about what constitutes stress and what can be done about it. Beliefs reflect, at least in part, socially shared assumptions about stress, coping, and health and may be considered cultural models of the individual and his or her social group. A significant example concerns cigarette smoking as a way of coping. Although smoking is widely recognized as a health-threatening habit in both low-SES and high-SES individuals, in low-social-status individuals smoking has often turned into one of their few available coping options and creates a feeling of rest and control when faced with distress. Further research on the social distribution of coping resources is certainly required.

Social Stress Models

Limbic Stress Processive Pathways

Adaptation to Stress

Transmitter Systems Adaptation

CRH Systems Adaptation

Vasopressin Systems Adaptation

Glossary

<i>Adaptation</i>	The situation in which repeated exposure to the same stimulus elicits diminishing responses from the body.
<i>Corticotropin-releasing hormone (CRH)</i>	Neurohormone secreted by the hypothalamus whose functions are related to stress, a primary activator of stress hormones.
<i>Limbic-hypothalamic-pituitary-adrenal (LHPA) axis</i>	The pathway regulating the secretion of stress hormones by brain limbic structures, hypothalamus, pituitary, and adrenal gland and involving release of corticotropin-releasing hormone (CRH) from the hypothalamus, adrenocorticotrophic hormone (ACTH) from the pituitary gland, and corticosteroid hormones from the adrenal gland.
<i>Neurotransmitters</i>	Chemical messengers released from different kind of nerve endings involved in the transmission of a nerve impulse.
<i>Social stress</i>	A highly complex set of neuroendocrine changes in response to the immediate social environment of the animal.
<i>Vasopressin (AVP)</i>	Neurohormone secreted by the hypothalamus, a major regulatory peptide, with CRH, for the secretion and synthesis of ACTH; initiates the hypothalamic-pituitary-adrenal (HPA) response to stressors.

Conventional models of physical stressors in laboratory animals show little validity with chronic human psychopathologies. Models of social stress based on the naturalistic events of interactions between conspecifics present a realistic model to include chronic

psychosocial stress in animals. Repeated or chronic psychosocial stress induce adaptation of various neurotransmitter and neuropeptide regulatory systems involved in the hypothalamus-pituitary-adrenal (HPA) axis response. Chronic stress impairs the cholinergic and adrenergic system-induced HPA response. The corticotropin-releasing hormone (CRH)- and vasopressin (AVP)-induced activation of the HPA axis follows distinct time courses. Complex transcription factor interactions and mechanisms accompany the activation of these neuropeptides during psychosocial stress.

Social Stress Models

The stress response is usually presented as adaptive physiological and psychological processes activated in animals and humans by various kinds of stressors. It is regarded as an alarm system that is initiated whenever the dynamic equilibrium of the living organism, called homeostasis, is threatened by physical and psychological events that are known as stressors. Current understanding of physiological mechanisms of the central stress response system is based on both clinical data and animal reactions to various physical stressors, such as footshock, forced swim, or immobility, which may elicit behavioral and psychological responses different from those evoked by psychosocial stressors. In socially organized mammals, however, the predominant stressors are not physical events but arise from the immediate social environment of the animal. The majority of stress stimuli in humans is of a psychosocial nature and contributes to the development and expression of disease. In order to study mechanisms involved in the etiology of human affective disorders, various animal models of social stress are used. Apart from genetic factors that predispose for psychopathologies, environmental stress plays an important role in the etiology of these mental diseases.

Common rodent and nonhuman primate models of social stress used in the laboratory with a focus on social hierarchy models contribute in complementary ways to the understanding of social stress. Animal models of social stress involve single, intermittent, or chronic exposure of a subject animal to a conspecific. The most frequently used models for rodents are the social defeat and the social colony models. In the social defeat model, a male intruder is introduced into the territory of another male, the resident

conspecific, which attacks and defeats the intruder. The desired outcome of the social conflict is ensured since the resident usually has higher body weight, is familiar with fighting, and frequently belongs to a more aggressive strain than the intruder.

In a social colony, male and female rats are living together in seminatural conditions and a social structure develops, with a single male being the dominant rat and the others subordinates. Social defeat stress induces major functional and structural changes in subregions of the hippocampal formation. Defeated or subordinate animals have an increased activation of HPA axis, demonstrated by an increase in blood adrenocorticotrophic hormone (ACTH) and corticosterone levels. Consequently, animal models that involve natural social context seem to be more appropriate because they represent situations that individuals may encounter in their everyday lives.

Crowding typically induces a social stress reaction with prominent psychosocial components, avoiding the physical components present in most typically used stressors and mimicking emotional state alterations. Randomly selected animals are placed together in housing cages such that each has less than a standard amount of space. In crowded rats, no agonistic interactions leading to dominance or subordination are encountered. The prototypical marker of the presence and magnitude of social stress is the activity of the HPA axis. Many responses to social stress appear to be quite consistent across various animal models, with only a few exceptions that may depend on the paradigm or species studied. Psychological stress is a good animal model for investigating the various behavioral and neurohormonal changes related to stressful circumstances.

Psychological stressors are associated with the activation of the sympathetic and adrenomedullary system and the HPA axis. These systems respond to psychological stress with increased output of noradrenaline from the locus coeruleus (LC) and noradrenaline and adrenaline from the adrenal medulla. The hypothalamus produces CRH, which activates the anterior pituitary gland to secrete ACTH, which in turn stimulates the adrenal cortex to secrete corticosteroids, primarily cortisol in humans and corticosterone in rodents. Negative emotional responses disturb the regulation of the HPA system. Relatively pronounced HPA activation is common in depression, with episodes of cortisol secretion being more frequent and persistent among the depressed than among other psychiatric patients and normal subjects. Chronic stress may induce a state of hyporesponsiveness of the HPA axis whereby cortisol secretion is attenuated.

Limbic Stress Processive Pathways

Psychological and neurogenic stressors requiring higher-order sensory processing of signals prior to initiation of a stress response recruit the limbic stress processive pathway. These processive stressors constitute stimuli that become stressful only by comparison with previous experience. Different types of emotional experience may involve different pathways and arise from activity initiated as a result of thoughts and memories in the cortex or as a result of activity initiated in the hypothalamus. The components of the limbic-sensitive pathways include prefrontal cortex, septum, extended amygdala, hippocampus, and hypothalamic nuclei. In contrast, the limbic-insensitive pathway is recruited by stressors that represent an immediate threat to homeostasis and does not require limbic structures. The amygdala and the hippocampus normally inhibit hypothalamic activity, but stress blocks this circuitry and thus leads to stimulation of hypothalamic releasing hormones such as the stress peptide. Both the hippocampus and the medial prefrontal cortex (mPFC) play an important role in the negative feedback regulation of HPA activity during physiological and behavioral stress. Chronic restraint and psychosocial stress can induce atrophy of hippocampal apical dendrites of CA3 pyramidal neurons, depletion of synaptic vesicles in mossy fiber terminals in CA3, and impairment of hippocampal-dependent learning tasks. Chronic elevations in corticosterone also induce a suppression in synaptic plasticity in the CA1 hippocampal field.

The amygdala is also a major extrahypothalamic source of CRH-containing neurons with high expression levels for the CRH-1 and CRH-2 receptors. Psychological stressors can activate the amygdala CRH system without evident activation of the hypothalamic CRH system; the amygdala CRH system is much more sensitive to psychological stressors than the hypothalamic paraventricular nucleus (PVN). The amygdala, in concert with other extrahypothalamic limbic regions, manifests the behavioral responses to stress, while the hypothalamic CRH system is important for modulating neuroendocrine responses to stress. The hippocampus is an important target of circulating adrenal cortical hormones that act on their receptors and are abundant in this structure. Stress affects glucocorticoid receptor and mineralocorticoid receptor gene expression in the hippocampus in a stressor- and gender-specific manner. Chronic exposure to high corticosteroid levels, during prolonged stress, can have a detrimental effect on hippocampal integrity and function and its excitation and plasticity.

Adaptation to Stress

Adaptation of a response to given challenge is one of the key features of the normal ability of an organism to cope with the external world. Social factors, as unavoidable real life events, are powerful modulators of the stress response. Adaptation to stressful challenges involves activation of neural, neuroendocrine, and neuroendocrine-immune mechanisms. The ability of the body to increase or decrease vital functions to a new state is termed allostasis, or stability through change. Allostasis actively maintains homeostasis and promotes adaptation. When the stress response is inadequate or excessive and the cost of restitution of homeostasis is too high, the resulting condition has been termed by McEwen allostatic load.

Physiological stress responses are accepted as beneficial in the short term but can be detrimental if over-activated or prolonged. Stress modulators regulate the extent, duration, and long-term impact of acute stress responses. Stress hormones are crucial mediators of both adaptive and maladaptive responses. Chronic stress induces changes in neuroendocrine and neuronal systems at several levels: in morphology of brain nuclei and neurons and in neurotransmitter and second messenger systems including single molecules. This also takes place in limbic brain structures that are under the influence of stress-activated systems. Within the limbic-hypothalamic-pituitary-adrenal (LHPA) system, chronic stress impairs the feedback-control mechanisms associated with decreased gene expression of corticosteroid receptors and structural alterations in the hippocampal formation. Prolonged stress reduces the inhibitory feedback exerted by the hippocampus over the hypothalamic CRH-producing PVN and consequently results in hypersecretion. Sustained stress leads to adrenal hyperactivity. LHPA axis alterations develop in all stressed animals independently of their position in the social hierarchy, whether dominants, subordinates, residents, or intruders, indicating that the HPA axis is more sensitive to the stressful nature of the situation and less modulated by the individual differences in the appraisal of the situation. Dysfunction of systems regulating CRH activity in the central nervous system (CNS) and LHPA axis dysregulation often contributes to the etiology of several psychiatric disorders, such as anxiety, panic disorder, posttraumatic stress disorder, and depression.

Challenging signals from the environment are communicated to the final cellular level of adaptation to stress to turn cascades of gene expression. Genes turned on by stress transcribe the information in their DNA code into messenger RNA (mRNA), which then

is translated into proteins making up the structure and adaptive functions of the brain and body. Proteins regulate the structural and energy dynamics of the cell, as well as the neurotransmitters, hormones, and signals of the psychoneuroendocrine system in mind-body medicine. A significant number of the genes in the human genome can be spliced together in different ways to generate alternative sets of proteins that modulate physiological adaptation in response to challenge and stress from purely physical to psychosocial levels.

Transmitter Systems Adaptation

Cholinergic System

Acute stress activates not only the HPA axis but also the septohippocampal cholinergic system in male rats. In the brain, acetylcholine (ACh) is one of the neurotransmitters clearly involved in the stimulation of hypothalamic release of CRH. Acute stress of immobilization increases the synthesis, binding, and release of ACh in the hippocampus and limbic structures. Chronic stress induces reduction of choline uptake and an increase in the number of muscarinic binding sites in the septohippocampal cholinergic system, which is involved in the pituitary-adrenal response to stressful stimuli. The social stress of crowding (21 rats placed in a cage designed for 7) for 3, 7, and 14 days considerably reduces the secretion of corticosterone induced by ICV stimulation of cholinergic muscarinic receptors. The reduced responsiveness of the HPA axis may be caused by a homologous desensitization and downregulation of central muscarinic receptors by an increased secretion of ACh during crowding stress. Homologous desensitization of muscarinic receptor may be regulated by β -adrenergic receptor-like kinase.

The function of the cholinergic system depends on the ACh gene, which codes for ACh and the acetylcholinesterase gene, which codes for the enzyme that hydrolyzes ACh and terminates the function of ACh excitatory neurotransmission in the CNS. Psychosocial stress can alter the cholinergic gene expression or splicing to generate alternative proteins that are involved in a variety of normal mind-body functions, as well as pathologies. Such stress-induced alternative gene splicing may constitute a major pathway in the modulation of gene expression by creative psychological and social processes.

Monoaminergic System under Stress

An important component of the stress response in the brain is the activation of monoaminergic systems.

The LHPA axis interacts with a variety of monoaminergic systems, including brain stem noradrenergic and serotonergic systems. Endocrine and central brain stem monoaminergic responses to stress appear to be precisely coordinated to facilitate adaptive physiological responses. Stress-induced stimulation of the noradrenergic/adrenergic, the serotonergic, and the dopaminergic system enables the brain to flexibly respond to challenges by reorganizing its neuronal networks. Acute stress stimulates noradrenaline (NA) release from terminal neurons in the LC, leading to depletion of NA, but repeated or prolonged stress restitutes NA levels in the brain.

Stress raises activity of phenylethanolamine-N-methyltransferase (PNMT), a specific enzyme that converts NA into adrenaline and accelerates turnover of brain NA and adrenaline.

In addition, stress-induced increased expression of the tyrosine hydroxylase gene may elevate NA concentrations. The release of catecholamines in the response to stressors is followed by an increase in the expression of genes that encode catecholamine-synthesizing enzymes by transcriptional mechanisms in the LC and the adrenal medulla. The persistence of transcriptional activation depends on the duration and severity of the stress. In response to an acute stressor, catecholamines stimulate some limbic regions, such as the hippocampus, amygdala, and hypothalamus, whereas the higher cognitive centers in the prefrontal cortex are inactivated. During stress, high concentrations of NA and/or adrenaline cause a decrease in a number of adrenergic receptors, termed downregulation, and low agonist concentrations upregulate adrenergic receptors. Adrenoreceptor (AR) downregulation may result from reduced expression of the receptor gene or proteolytic degradation of receptor molecules. A reduced number of functional receptors results in desensitization of the respective receptor system and impairs its biological response to an agonist. Receptor molecules may be desensitized by phosphorylation through protein kinases, rapid uncoupling from its effector unit, sequestration from the cellular membrane, and internalization into the cytoplasm and intracellular vesicles. Chronic psychosocial stress reduces the number of adrenergic receptors in brain regions that regulate emotional behavior depending on the duration of the stress period and brain regions. In the LC, α_2 -AR binding is already reduced 2 days after the onset of the stress and remains at a low level. Diminished autoreceptor activity impairs feedback inhibition of NA release and, consequently, higher levels of the neurotransmitter in projecting regions of the LC. During chronic psychosocial stress, α_2 -AR expression

alters from initial downregulation to later upregulation, inducing first high and then low levels of NA.

Stress-induced downregulation of brain β -ARs is regarded as an important mechanism of adaptation to stress. Repeated or chronic stress induces high levels of endogenous agonist NA, and adrenaline causes rapid β -AR internalization into the cells and their functional desensitization. This is considered one of the biochemical mechanisms in receptor adaptation performed in order to prevent dangerous effects of the persisting stress-induced high levels of catecholamines. The psychosocial stress of crowding for 3–7 days considerably reduces the secretion of corticosterone elicited by ICV β -adrenergic receptor agonist and evokes progressively lesser diminution of that response after 14 and 21 days of crowding. In brain cortex α_2 -ARs are temporarily downregulated after 2 days of stress but upregulated after 4 weeks. Stress rapidly desensitizes the β -AR system via receptor sequestration and internalization, but some of these changes are only transient since internalized β -ARs can reinsert into the plasma membrane and restore normal receptor numbers. Social crowding stress only moderately diminishes the secretion of corticosterone evoked by ICV α_1 -adrenergic agonist. Adrenergic receptors, like the cholinergic muscarinic receptor, are linked to G-protein and are regulated by phosphorylation, which regulates desensitization of receptors to their agonists. Phosphorylation of the β -adrenergic receptor by cAMP-dependent kinase and protein kinase C (PKC) during stress is intimately involved in the desensitization of the receptor. The brain, and specifically the hippocampus, have large neuronal plasticity for a successful adaptation to a stressful situation that occurred previously. Changes that occur in the hippocampus are accompanied by alterations in the other brain regions functionally related to the hippocampus. Reacting and changing neurotransmitter systems in brain areas interact in a coordinated fashion aimed at maintaining stability through change in physiological coping mechanisms during stress.

CRH Systems Adaptation

The most well-known hypothalamic peptide whose functions are related to stress is the CRH, which may be regarded as a primary activator of the LHPA system. Produced by many neurons throughout the brain, CRH functions as neurotransmitter. CRH and noradrenergic neurons of the central nervous stress system innervate and stimulate each other in a positive feedback mechanism. CRH given ICV in rats activates the HPA axis and the sympathetic nervous

system. Stress activates hypothalamic as well as extra-hypothalamic CRH neuronal pathways. In response to a stressful stimulus, CRH is released into the hypothalamic-portal blood from neurons in the PVN of the hypothalamus, the site of convergence for stress signals in the brain. Hypothalamic CRH acts as a major mediator of the mammalian stress response by stimulating pituitary pro-opiomelanocortin (POMC) gene expression and ACTH secretion that, in turn, stimulates release of glucocorticoid from the adrenal gland. CRH stimulates POMC gene transcription in pituitary corticotrope by several transcription factors. The transcriptional activation of the pituitary POMC gene by CRH is associated with inhibition of nuclear transcription factor NF- κ B DNA-binding activity and with activation of the activator protein-1 (AP-1) factor. CRH activates target pituitary cells and neurons via distinct genes encoding membrane CRH-R1 and CRH-R2 receptors. Stress causes marked increases in the expression and cell content of CRH-R1 receptors, which predominantly mediate the CRH-induced hormonal response to stress. CRH released within the PVN increases cAMP levels, and sequentially facilitates CRH transcription, via cAMP response-element binding protein (CREB) phosphorylation and later limits the transcription via induction of the inducible cAMP early repressor (ICER). Fine modulation of CRH expression depends on a complex balance between activation by phospho-CREB and repression by ICER late during stress. Induction of ICER could serve as a protective mechanism to limit transcription of hypothalamic CRH and avoid pathological consequences of excessive expression of neuropeptide in response to stress.

Precise regulation of circulating glucocorticoids is critical for preserving homeostasis under stress conditions. Excessive CRH production may lead to HPA axis dysfunction and psychiatric disturbances. The inhibitory isoforms of CRE modulator induced during stress contribute to the decline in CRH gene transcription during persistent stimulation.

Vasopressin Systems Adaptation

In the initiation and modulation of the HPA axis response to acute and psychosocial stress both CRH and AVP are involved. These two major regulatory peptides for the secretion and/or synthesis of ACTH are colocalized in the parvocellular neurons in the PVN in both humans and rodents. These peptides, colocalized in the same secretory granules at the nerve endings of the median eminence and coreleased into the portal circulation, exert synergistic effects on ACTH secretion from the anterior pituitary. Apart

from presence in the hypothalamus, CRH and AVP are localized in several other limbic and brain structures. A variety of acute and chronic stressors alters their concentrations in the hypothalamus and several other brain regions.

In pituitary corticotrope, the vasopressin V1b receptor isoform is specifically expressed and plays a crucial role in regulating HPA axis activity during stress and in resting conditions. Under stress conditions, both the hypothalamic AVP/V1bR and the CRH/CRH R1 system are required to maintain normal HPA axis regulation. Acute stress results in a rapid increase of CRH heterogeneous nuclear RNA (hnRNA) at the time of maximal ACTH secretory response. The stress-induced AVP hnRNA response in the parvocellular neurons is slower in onset than that of primary CRH transcript, with a maximum at 2 h after challenge. Differences in timing of CRH and AVP hnRNA responses indicate distinct mechanisms underlying stress-induced activation of these genes. Physical or psychological stressors activate the CRH and AVP in the parvocellular neurons of the PVN, the major regulators of ACTH secretion. The AVP gene is upregulated by cAMP. The promoter of the AVP gene contains cAMP response element (CRE), and the promoter activates of transfected AVP gene are upregulated with cAMP. The dual CRH/AVP regulatory system may benefit the organism in coping with various stressful events. The release of CRH and AVP peptides is regulated differently depending on the nature and the duration of the imposed stress. Prolonged stressors induce a gradual shift from a CRH-predominant stress response to an AVP-predominant response after chronic stress. These adaptational changes could partly depend on glucocorticoid receptor changes induced by repeated stress in the PVN and the hippocampus and the greater responsiveness of AVP than CRH to chronic stimulatory inputs. CRH and AVP regulate MR and GR in the hippocampus and anterior pituitary, structures with the highest levels of MR and GR mRNA and receptor protein in the CNS. These GRs have an important role in the regulation of the LHPA axis and stress adaptation and the pathophysiology of stress-related disorders.

AVP and CRH bind to specific pituitary corticotrop membrane receptors that activate different second messengers. The rat pituitary AVP receptor is coupled to phospholipase C, and the CRH receptor to an adenylate cyclase. Repeated stress induces rapid adaptation of the CRH mRNA response and desensitization of the pituitary ACTH response, which may be caused by negative feedback mechanisms, as well as depletion of the releasable ACTH pool or down-regulation of pituitary CRH receptors. On the other

hand, chronic stress or repeated exposure to identical short-term stressors may induce an increased pituitary responsiveness due to sensitization of pituitary corticotrops to CRH. The social stress of crowding for 3 days facilitates the ACTH response to CRH and corticosterone response remains unaffected, indicating that the HPA system is fully sensitive or even hyperactive. This may reflect predominantly moderate upregulation of pituitary CRH system. Crowding stress considerably reduces the AVP-induced ACTH and corticosterone response. This results from desensitization and/or decrease in the number of AVP receptors in the anterior pituitary corticotrops or from desensitization of the AVP-stimulated intracellular inositol triphosphate and the PKC signaling pathway. AVP plays a primary role in the regulation of the pituitary adrenal axis during adaptation to stress. Chronic stress increases the expression of AVP in parvicellular neurons of the PVN, and secretion of AVP but not CRH into the pituitary portal circulation. Changes in density and sensitivity of pituitary AVP receptors may play a major role in adaptation of the HPA axis to crowding stress, as with adaptation to chronic psychosocial stress.

Social Support as a Mechanism for Coping with Stress

Social Support as a Source of Stress

Summary and Conclusion

Glossary

<i>Anticipated support</i>	Support perceived to be available if the need for it arises in the future.
<i>Appraisal support</i>	Feedback relevant to self-evaluation.
<i>Emotional support</i>	The provision of empathy, reassurance, liking, and respect.
<i>Informational support</i>	Help with problem solving and advice.
<i>Instrumental support</i>	Aid with services and the tasks of daily living.
<i>Social network</i>	The group of individuals with whom an individual may exchange support.

This article examines the concept of social support and its relationship to stress. A brief review of several illustrative theoretical perspectives of social support is presented first. Next, an outline and overview of the research focusing on social support as a coping mechanism is provided, followed by a discussion of social support as a source of stress and a brief summary and conclusion.

Theoretical Perspectives

Social support has received a great deal of attention in the last several decades. There are some points that are now relatively well accepted: social support tends to be cumulative over the life course; it is often multi-generational; it is best when an individual both provides and receives support, although not necessarily in the context of the same relationship; and it can include exchanges between family and friends and between formal and informal providers.

Research thus far has offered interesting and sometimes quite useful evidence for how social relations affect the individual's socialization, development, coping, and general well-being. The concept of social support has been attractive to researchers in a wide variety of disciplines, including epidemiology, sociology, psychology, social work, and health care. The related theoretical perspectives or frameworks offered by each of these disciplines are too numerous to mention here; instead, illustrative examples are provided.

Epidemiologists offered some of the earliest theorizing about the role of social support and health. Researchers in this field suggested that social relations help protect the individual from disease. This perspective was initially considered quite revolutionary because these researchers claimed that physical as well as mental health could be influenced by social relations. More recently, other researchers have found empirical support for this perspective.

Kahn and Antonucci extended this notion by suggesting that individuals are surrounded by convoys of family and friends. The resulting interaction and socialization processes teach them the roles and responsibilities of childhood, adulthood, and old age. This convoy of relations is assumed to have a positive effect, helping the individual successfully meet the challenges of life. However, it is recognized that convoys may not always be positive and sometimes can expose individuals to stress rather than serve as protection. This theoretical framework suggests that social support is best understood within a life course perspective and that social interactions are cumulative and developmental.

These theoretical frameworks were general and broad; other theories have taken a more practical approach to understanding social support. Cantor's hierarchical theory of social support suggests that a natural hierarchy of people exists from whom an individual prefers to receive support. People prefer to receive support from a spouse and children first and then turn to friends and neighbors if the former are unavailable. Only if all of these informal sources of support are unavailable are people likely to seek support from a formal provider (e.g., government and community institutions). A somewhat complementary theory was offered by Litwak, who suggested that people turn to those who are most able to provide the specific goods or services they need rather than to those to whom they feel closest. Both of these theoretical perspectives have a practical task-oriented focus.

Some theories have been more psychologically focused. For example, Pearlin argued that others step in when needed and help the individual achieve his or

her goal. This provides the individual with a feeling of ability or personal achievement, which not only aids in coping with a specific event but also provides the individual with a more generalizable sense of mastery. This theoretical perspective is similar to that offered by Antonucci and Jackson, who suggested that there is a life-span developmental benefit to the constant repetition of supportive interactions. Receiving support over time leads to viewing oneself as worthy, cared for, and loved. Under optimal conditions, this exchange provides the individual with a sense of personal efficacy that is critical as the individual faces the challenges or crises of life.

The types of theoretical perspectives that have guided research in this area can be summarized as follows: (1) general broad-based theories suggesting that social relations affect an individual's ability to resist stress and disease; (2) more practical, task- or person-specific theoretical frameworks that provide guidelines for determining who is the logical choice for helping a person cope with a specific problem, task, or crisis; and finally (3) more global, developmental perspectives that are designed to explain how an individual develops the ability to cope with stress over time. We turn now to a consideration of the evidence that examines how social support influences the individual's experience of stress.

Social Support as a Mechanism for Coping with Stress

It is well established that social relationships influence individuals' psychological well-being by providing love, intimacy, reassurance of worth, tangible assistance, and guidance. Across the life span, the lack of high-quality relationships is associated with negative physical and psychological consequences such as anxiety, depression, loneliness, and poor health. Studies of social support and well-being generally reflect two lines of research. First, support is thought to have direct effects on health maintenance and recovery, enhancing well-being regardless of the level of stress experienced. Second, support has been conceptualized as having indirect effects on well-being by acting as a buffer against stress. According to this second approach, during stressful events social support mediates the association between stress and adjustment so individuals who have high-quality support are not as negatively affected by stress as those who have less adequate support. Research provides evidence for both models. In this section, however, we focus on conceptualizing support as a buffer against stress.

Empirical studies provide evidence that social support can reduce the negative impact of stress associated with physical illness, unwanted or unexpected

life events, and developmental transitions. For example, supportive relationships with family members and friends can help children cope with stress associated with school transitions, young adults adjust to the birth of a child, or older adults negotiate retirement. In particular, having a confidant appears to be an especially helpful resource in coping with stress. Recent evidence highlights race, ethnicity, and culture as important factors in links between stress and social support. For example, studies suggest that social support can buffer ethnic minorities from the stress associated with discrimination.

Social support is most effective as a buffer against stress when the support matches the needs elicited by the stressor. Researchers discuss four main types of support: emotional, appraisal, informational, and instrumental. Different types of support are more appropriate as buffers against some stressful experiences than others. For example, bereavement may call for emotional support, and illness may call for instrumental support.

Researchers also distinguish between the perceived availability of support and the actual receipt of support. Available or anticipated support is the belief that social network members are willing to provide support if the need for it arises in the future. Anticipated support and received support have different effects on psychological well-being. It appears that the perception that support is available if needed has direct positive effects on well-being but that actually receiving support is not always beneficial. In particular, received support may not act as a buffer against stress because receiving support may be a signal that an individual's own coping resources have been inadequate in resolving the stressful situation. Individuals are likely to try to deal with stress on their own before turning to others for help. Thus, receiving support may indicate that their own efforts have failed and in some sense counteract the beneficial effects of the support. In addition, receiving support may place burdens on the support network and lead to conflicts among members. Anticipated support, on the other hand, promotes individuals' own coping efforts, helps individuals maintain hope that others are available if needed, and reflects a sense of caring and commitment from the social network.

It is important to recognize that the presence of a social relationship does not necessarily indicate that the relationship is supportive. The overall quality of the relationship is more important than its mere existence. For example, Major and colleagues found that supportive relationships could help women cope with the stressful experience of having an abortion. If these supportive relationships were also perceived as being high in conflict, however, the women showed

more distress than if the relationships were low in conflict. Among women who did not perceive their relationships as supportive, there was no association between conflict in these relationships and distress. Thus, in considering whether relationships can act as buffers against stress, it is important to consider their negative as well as supportive characteristics.

To summarize, a great deal of evidence suggests that social support can help individuals cope with stress. To be most beneficial, this support should match the needs elicited by the stressor and be provided or expected in the context of a high quality relationship.

Social Support as a Source of Stress

The fact that social support can have negative consequences for the individual has only recently been addressed, and researchers are now openly calling for more attention to this issue. Social networks can become a source of conflict, stress, and sometimes health-damaging effects. One important dimension to this approach is the finding that larger social networks do not guarantee happiness, nor do they necessarily create a buffer from stress. For example, larger social networks are associated with greater stress among women, especially due to role strain. A case in point is role overload, a situation in which demands are placed on an individual that exceed his or her capacities to cope with them. For example, the responsibilities of informal caregivers to seriously impaired relatives may compete with other demands of a social network, resulting in a significant amount of stress for the individual. Having more social contacts "not only provides more potential resources but also may create additional demands on time and increase the probability of interpersonal conflicts" (Cohen and Syme, 1985: 12). Nevertheless, role theorists, such as Coontz, have noted that multiple roles are also associated with multiples sources of satisfactions, reward and accomplishments, thus suggesting the picture is not a simple one.

The most recent findings about social relations as a source of stress provide some insight into biopsychosocial links. When social relations are negative in nature, physiological reactivity becomes heightened. For instance, hostile spousal interactions increase heart rate, blood pressure, and neuroendocrine reactivity, as well as compromising immune functions. Moreover, negative social relations earlier in the life course directly affect physiological reactions later in life, contributing to allostatic load, which in turn may accelerate disease and poor mental health. This new body of research suggests that social relations influence physiological stress indicators and

that, furthermore, the effects may be lifelong and cumulative.

Assistance from family is often thought to be the most reliable and consistent source of social support, yet family members who provide social support during times of crisis are themselves the sources of stress at other times. Moreover, negative interactions are more likely to involve kin than nonkin. Family also tends to make up the majority of individuals' social networks as they age. Thus, the source of stress is often found through the relationships that unfold within the confines of family support situations. For example, divorced women with social networks dominated by family may be more criticized for their failed marriage and thus experience significantly more, rather than less, stress.

Morgan conducted focus group discussions with recently widowed women and men to explore whether social networks actually ease adjustment to widowhood. The discussions revealed that a significant portion of negative outcomes derived from relationships with family members. Morgan stated that his findings may generate useful hypotheses about the role of family and friends as sources of support by suggesting that a distinction be made between positive and negative aspects of relationships. Support from family often produces stress when discrepancies exist between expectations and actual performance.

High levels of social support have also been found to cause stress. For example, research with the elderly demonstrates that such high levels of support from caregivers may cause stress and thus be harmful to the elder's well-being. Similarly, research has shown that family assistance to adolescent mothers helps them cope with many stressful aspects of their experience, but this support often is accompanied by conflict, frustration, disappointment, and stress. Too much support may foster dependency, causing the receiver to lose autonomy and hence develop low self-esteem. Another example is chronic financial strain. Stack found that survival in a poverty-ridden community depended on financial support from social network members. Support of this type, although generally positive, could under certain conditions be problematic. Having others expect support can also limit the success of the support provider. The network members they turn to for support in the face of chronic financial stress are likely to be facing financial difficulties of their own. The issue is complex. Social support can help minorities cope with the harmful mental and physical health consequences of racial discrimination. Jackson, Williams, and Torres hypothesize that, although negative health outcomes are associated with the stress of discrimination and the related experience of social inequality and racism,

these effects can be successfully buffered by social support. At the same time, it has been noted that having a strong group identity may elevate individuals' perceptions of discrimination and in some ways make them more vulnerable to its effects.

Summary and Conclusion

Many theorists from several different disciplines have developed frameworks regarding the association between social support and stress. Empirical investigations of these theories have revealed that social support can help individuals cope with stress but that social support also can be a source of stress. These theories and research suggest that social support can be a complicated matter with both positive and negative implications for individuals and their ability to cope with the stress and challenges of everyday life.

Social Support and Traumatic Events
Fluctuating Social Support in Times of Crisis
Social Support and Posttraumatic Stress Disorder

Glossary

<i>Perceived support</i>	Perceptions of helping and support behavior by others.
<i>Received support</i>	The actual experience of helping and support behaviors.
<i>Social embeddedness</i>	The extent to which the individual has active ties with family, relatives, friends, work colleagues, and other members of the community. The size, density, and

	reciprocity of the social network are all important.
<i>Support deterioration</i>	The reduction in perceived support and social embeddedness that may take place following trauma and disaster.
<i>Support mobilization</i>	The activation of helping and support behaviors in times of trauma.

Social Support and Traumatic Events

Everyone has to deal with traumas of varying forms in his or her life. These can be personal, such as the diagnosis of a serious illness, involvement in an accident, or unexpected death of a relative; or traumas can occur on a larger scale in the community when disaster strikes. Disaster can strike unpredictably at any time and in any place. Even when disasters do not lead directly to injury, they can have devastating effects on mental and physical health, on economic well-being, and on the structure of a society. The impact of disasters depends on many factors, including the location, context, and the actual form the disaster takes. The location of a disaster affects people's access to help and the availability of resources. For example, the 2004 Indian Ocean tsunami devastated remote areas of several countries, and it took many days before assistance was received. The context of a disaster is very influential; in some cases, survivors can lose their possessions, homes, and livelihoods, with long-term consequences for health and well-being. The form of the disaster – whether it is a natural disaster, involves humanmade objects (such as trains or nuclear power plants), or is deliberate (in the case of terrorism) – also make a difference. A recent authoritative review of some 160 samples of disaster victims concluded that mental health outcomes were worse for young people, victims from developing countries (compared to those from developed countries), and victims who experienced mass violence such as terrorism or shooting sprees (compared with natural or technological disasters). At the same time, there is great variation in responses to disaster. Worse mental health outcomes and more stress symptoms are commonly observed in women (compared with men), ethnic minority groups, people exposed to more severe stress, people with other severe stresses in their lives, and people with previous psychiatric problems.

Research on how people cope with disaster and trauma and rebuild their lives has focused on the psychological and material resources that are mobilized to help them. Prominent among these is social support. It may seem obvious that social support is a good thing in situations of trauma and disaster. The news media regularly depict neighbors, friends, and even strangers rallying round when a disaster strikes.

But the reality is far more complex. Often, the acute mobilization of support is not sustained in the long term, and the people who need support most are not necessarily the ones who receive it.

Social support is multidimensional. Two broad types of support can be offered in times of trauma: emotional support (comfort, sympathy, and reassurance) and practical support (food, shelter, money, advice, etc.). Social support takes place within a social and community context, and the extent to which the individual is socially embedded (has relationships within the community) is crucial. There are also important differences between received and perceived support that need to be taken into consideration. Social support is related to the individuals' socioeconomic circumstances. For example, contrary to the widely held belief that social support might be stronger in lower-socioeconomic groups due to extended ties and the values placed on social connectedness, research has shown that it is often actually lower in these groups. Mickelson and Kubzansky explain that, whereas middle-class communities can pool their resources to help those in need in times of stress, in more disadvantaged populations these resources are already stretched. Social support levels are very fluid. They depend on whether the trauma affects one individual or affects a whole social network. Studies of how social support operates during disaster and trauma has led to the recognition of the importance of concepts such as support mobilization and support deterioration.

Fluctuating Social Support in Times of Crisis

There is typically a strong mobilization of helping behavior when disaster strikes. However, the research shows that certain stressful events in people's lives can lead to a decline in social support. Divorce, the death of a loved one, the loss of a job, and illness are not only stressful in themselves but can also lead to a significant change in the availability of social contacts. There are indications that in these circumstances the decline in social contacts can itself be an additional stressor. For the individual whose partner was his or her main source of emotional support, comfort, and advice, the partner's death means that this support can no longer be called on to help in the coping process.

Similar factors may operate in disaster situations. Early research by Kaniasty and Norris was carried out with victims of floods in Kentucky in the 1980s. These disasters occurred at the same time as ongoing research that involved measures of social support, making it possible to compare support levels in the

same community both pre- and posttrauma. It was found that the victims of floods reported that less social support was available after the disaster than before. Their perceptions and expectations of support were not fulfilled. Consequently, the psychological impact of the disaster was magnified; people were not only stressed by their losses but also by the deterioration of perceived social support. This disaster took place in an impoverished rural community where there were few surplus resources.

Later research carried out in the context of two major hurricanes (Hurricane Hugo and Hurricane Andrew) broadly supports these findings. In the short-term (up to 12 months after the disasters), poor mental health is positively associated with greater direct exposure to the hurricane and is negatively related to perceived support. But perceived support was lower in people with greater direct exposure because those who were more in need were more likely to feel that support had fallen short. In the longer run, mental health was more closely associated with perceptions of support than with the extent of exposure to the disaster.

Kaniasty and Norris also examined the different ways in which social support is influenced by the context of the crisis, studying two towns in Mexico that were affected by severe floods and mudslides in 1999. The towns had very different experiences of the disaster. In one (Teziutlan), a whole mountain region was destroyed, so survivors were moved to a new community outside the original city. Flooding was worse in the second town (Villahermosa), but in this case victims were not moved. These communities were studied at several time points from 6 months to 2 years after the disaster. This allowed changes in the ratings of social support to be examined. At 6 months after the disaster, the people of Teziutlan reported less perceived support and less social embeddedness than the residents of Villahermosa. At the 2 year follow-up, the reported levels of social support in Villahermosa had improved markedly, whereas in Teziutlan they remained below normal. Social support was particularly low among women and people of lower social status.

Social Support and Posttraumatic Stress Disorder

The consensus in the literature is that social embeddedness and received support are beneficial for the mental health of disaster victims. Lack of social support is also a strong risk factor for posttraumatic stress disorder (PTSD), an effect that has been observed across a range of study populations. Interestingly, it appears that the level of social support

available at the time of the trauma and after the trauma is crucial to the development of PTSD symptoms. The levels of social support measured before the trauma are less predictive, probably because perceptions of support may not match reality. But relationships can be complicated. One study of police officers in New Zealand examined the effect of support from peers, from supervisors and from people outside work on the development of PTSD symptoms following exposure to severe trauma. Although levels of support did help to explain some of the variation in PTSD, it was found that being able to talk to others about the negative aspects of the work was actually associated with more, rather than fewer, PTSD symptoms. Fostering the right atmosphere for social support in organizations in which staff may have to deal with high levels of trauma can be of benefit.

The extent to which the observational research on social support and trauma can be translated into active support services by health professionals is controversial. The fact that the people who report low support from their friends and families experience greater psychological distress than others does not mean that remedial support by health and emergency personnel will necessarily be beneficial. There is growing evidence, for example, that some early psychological interventions such as debriefing can do more harm than good. Similarly, research on patient support groups indicates that these can have deleterious as well as beneficial effects. Victims of disasters can be reluctant to seek or accept psychological help. It may be that social support interventions are best delayed for a number of weeks after a disaster, prioritizing more acute needs. It is only after the disaster situation has settled down to some extent that victims are prepared to focus on emotional needs. Further research is needed to extend knowledge of how communities affected by disaster could be supported to aid the sustained mobilization of social support, whether support interventions are possible, and which approaches are most beneficial for those at risk.

Psychosomatic Disorders

Stress and the Onset of Organic Disorders

Medically Unexplained Symptoms

Anxiety and Depressive Disorders

Glossary

<i>Anxiety disorder</i>	A disorder of mood characterized by tension and worry, often accompanied by physical symptoms of tension, including palpitations, butterflies in the stomach, and breathing difficulties.
<i>Chronic social difficulties</i>	Ongoing environmental stressors such as unemployment, serious financial or health difficulties, and ongoing serious difficulties in close relationship.
<i>Depressive disorder</i>	A disorder of mood accompanied by sleep, appetite disturbance, lack of energy and concentration, and possibly ideas of suicide.
<i>Life event</i>	A discrete change in the person's immediate environment, such as a bereavement or a marital separation.
<i>Medically unexplained symptoms</i>	Symptoms of pain or function (e.g., bowel or breathing disturbances) that cannot be explained on the basis of underlying organic disease.

Organic disease

A physical disease understood on the basis of recognized tissue damage.

Psychosomatic medicine

The study of biological, psychological, and social aspects of all diseases.

Psychosomatic Disorders

Psychosomatic disorders were previously thought to be a separate group of disorders in which stress and psychological distress led to disease. Examples were peptic ulcer, arthritis, and dermatitis. It is now recognized that all diseases may have social, psychological, and behavioral aspects as well as physical organic features. The World Health Organization defines psychosomatic medicine as “the study of biological, psychological and social variables in health and disease.”

This is best illustrated by the example of heart disease. Heart disease is caused by many factors. These include inherent biological factors, including age, sex, and genetic enhancement, that increase the chances of a heart attack; physiological factors, such as raised blood pressure, smoking, alcohol consumption, and increased blood cholesterol level; and psychological and social factors, which include depression, anxiety, and certain forms of stress, which are associated with an increased chance of developing a heart attack or increased chance of dying thereafter. Stress may lead to anxiety or depressive disorders, which can lead to a fast heart rate and increased chance of irregular heart beats, which may be fatal soon after a heart attack. Lack of social support – in the form a close person with whom all difficulties or problems can be shared – also contributes to increased chance of further heart attacks.

Thus, the modern view of psychosomatic mechanisms includes a role for stress, depression, and lack of social support alongside biological factors in the causation or outcome of disease. The relative importance of environmental stress varies in different conditions.

Stress and the Onset of Organic Disorders

Stress is much less important than the other biological or physical causative factors in the development of a heart attack. There is no clear link between stressful life events (e.g., marital separation and loss of job) and having a heart attack. There is a link with more chronic stress – 40% of heart attack patients have experienced a chronic social difficulty concerning work, money, or housing compared to 17% of healthy controls. The greatest difference seems to be in the excessive hours worked and lack of proper holidays. This seems to be something that individuals bring on themselves by working excessively hard (i.e., the type A personality).

In other diseases, different patterns have been reported. In peptic ulcer, for example, life events are important, especially those that engender goal frustration. These events involve working hard toward a particular goal for many years and then being thwarted by a change of circumstances at the last moment. Such an event occurred in over half (54%) of people with peptic ulcer, compared to only 9% of healthy comparison groups.

Another stress is that of a major earthquake. There was an increase in the number of people with stomach ulcer after the Hanshin-Awaji earthquake; for most people, the ulcer developed in conjunction with an infectious agent in the stomach, *Helicobacter pylori*, but among those physically injured following the earthquake stomach ulcers developed independently of this infectious agent. Thus, there is a clear relationship with stress, which must be considered alongside other risk factors for peptic ulcer – *H. pylori* infection, drugs taken for arthritis smoking, and an inherited predisposition.

There is a discernible increase in environmental stress prior to the onset of stroke, but the effect is weak – the biological factors listed as risk factors for heart disease are much more important. In one study, 24% of stroke patients and 12% of controls had experienced a severe life event in the year prior to the stroke. This is a much smaller difference than that found in peptic ulcer.

It is easy to assess life events prior to the onset prior of a heart attack or a stroke because these conditions develop at a clear point in time. In multiple sclerosis, however, the onset is much less clearly defined. It

does appear that the experience of a severe life event during the 6 months prior to the onset of multiple sclerosis is very considerable – 62% of multiple sclerosis patients had experienced such an event, compared to only 15% of a control group. If this result is confirmed, it suggests that the experience of stress probably interacts with the immune system, which may have been sensitized by exposure to an infection during childhood or early adulthood.

Stress and the Immune System

One of the most likely ways that stress leads to the onset of organic disease is by the modification of the immune system. This has been shown in very well-controlled studies of susceptibility to infection with the cold virus. An impressive feature is the dose-response relationship between an index of psychological stress and chance of infection; that is, the more stress experienced, the greater likelihood that a cold will develop after experimental exposure to the virus. The psychological stress in these studies comprised a combination of stressful life events (environmental stress) and the degree of distress (symptoms of anxiety and depression).

In order to exclude the interference with biological variables, these studies controlled for a number of variables that might explain the stress-infection association: smoking, alcohol, exercise, diet, quality of sleep, number of white cells in the blood, and total immunoglobulin levels. The researchers also excluded the effect of personality variables of low self-esteem, personal control, and degree of extroversion and introversion. When this is done, there is a clear link between the stress levels of the caregivers of people with Alzheimer's disease and immune response, measured by the antibody response to influenza vaccination.

Medically Unexplained Symptoms

By contrast to the pattern observed in organic disease, there seems to be a very clear increase in stress just before the onset of certain disorders in which no organic disease can be found to explain the symptom. Typical disorders are irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia. The symptoms may be severe (e.g., pain) and may lead to an operation, such as an appendectomy although the appendix appears to be quite normal. The pain may also lead to many investigations that fail to reveal any recognized organic disease to explain it. Approximately two-thirds of such patients have experienced recent environmental stress, compared to less than one-quarter of people with organic disease.

or healthy control subjects. This pattern of recent stress is similar to the stress that occurs prior to depressive disorders.

Anxiety and Depressive Disorders

The most common reaction to environmental stress is depression or anxiety, which, if severe and/or prolonged, amounts to anxiety or depressive disorder. Bereavement is a typical environmental stress that may be followed by the onset of depression; it may also be associated with the increased onset of serious physical illness. The mortality of widowers has been shown to increase 40% during the 6 months following the loss of their wives.

This means that the combination of a physical (organic) disorder and concurrent anxiety or depressive disorder is common; approximately one in five people with a serious and/or disabling physical illness have concurrent anxiety or depression. Depressed people with physical illness experience more severe pain, view their illness more seriously, and feel that the chance of recovery is lower. This view of the illness can lead to a delay in the return to normal activities, such as return to work or resuming a normal sexual relationship after a heart attack.

A woman with rheumatoid arthritis, for example, whose husband also has a disabling illness can be described as being under stress, partly because of her own illness and partly because of her husband's illness. These two stresses may lead to depression, in which case the pain worsens and the illness appears to be worse. Her going to a rheumatology clinic may lead to a change in the treatment for her rheumatoid arthritis, but only if the depression is recognized and treated will the patient's health begin to return. For

this reason, modern medicine is increasingly keen to identify anxiety and depressive disorders in patients with chronic diseases, as well as the accompanying environmental stress.

Summary

Glossary

<i>Atrophy</i>	A diminution or degeneration of bodily tissues or organs.
<i>Baroreceptors</i>	Neural structures located throughout the cardiovascular system that transmit nerve signals to the central nervous system in response to changes in blood pressure and initiate an involuntary nerve response (baroreflex) that brings arterial blood pressure back toward normal.
<i>Cardiac output</i>	The quantity of blood pumped by the heart each minute; the product of the amount of blood pumped each time the heart contracts (stroke volume) and the number of times the heart beats (heart rate).
<i>Hydrostatic pressure</i>	The pressure created from the weight of a column of fluid due to the presence of gravity. On Earth, hydrostatic pressure increases 1 mmHg for each 13.6 mm distance below the surface of the fluid column.
<i>Ionizing radiation</i>	Energy imparted by radiation to an atom that results in the ejection of an electron and the creation of an ion.
<i>Maximal O₂ uptake</i>	The maximal capacity for consuming and using oxygen (aerobic capacity) by the body tissues.
<i>Muscle fiber</i>	An individual muscle cell.
<i>Orthostatic intolerance</i>	The inability to tolerate the upright posture due to low blood pressure and reduced blood flow to the brain, leading to symptoms such as lightheadedness,

dizziness, blurred vision, and possible fainting.

Stress

A challenge to homeostasis that is accompanied by a change in physiological function.

Introduction

Human physiology and health have evolved and adapted in the presence of Earth's gravity. The physical stress imposed by movement in the presence of gravity manifests itself in a dramatic elevation in energy exchange, reflected by such physiological responses as increased oxygen uptake, respiration, heart rate, and sweating. The magnitude of physical stress associated with the development of the force required by muscles to perform various physical activities such as moving one's body or lifting or throwing objects is dependent on the level of gravity opposing these actions. Thus, gravity has traditionally been considered the primary constant stress factor for influencing adaptation and maintaining the health of the human body on Earth. However, the evolution of travel and habitation of humans in space, and the associated absence of gravity, has imposed new physiological adaptations via a reduction in hydrostatic pressure gradients within the cardiovascular system, a decreased weight load on the muscles and bones, and a lower energy requirement and/or output. The space environment is unique in that the physiological stress normally associated with the maintenance of health on Earth is altered as a result of reduced gravitational accelerations and factors related to confinement in a closed ecological environment. This article describes numerous physiological adaptations and responses associated with travel to space and planets with lower gravitational forces than Earth that can compromise normal function and health, particularly on return to Earth.

Stress Environment of Space

Space exposes astronauts to extreme environmental and psychological conditions imposed by a variety of stressors that result in a pronounced compromise to their safety and health, both in the space environment and on return to Earth. Immediately on entry into orbit, the relative absence of gravity results in unloading of the body tissues; external light-dark cycles occur every 90 min, disrupting normal circadian rhythmicity and ultraviolet light is nearly abolished;

microflora proliferate in the air and water and carbon dioxide levels within the enclosed space craft are chronically elevated. The crew members are required to exercise vigorously during long-duration space missions, often more intensely than they did before flight in an effort to maintain their baseline fitness and reduce the physiological decompensation associated with space flight. Psychological stress levels that can lead to significant neuroendocrine effects on physiological functions may become elevated when diverse crew members are required to exist in relatively confined living quarters, with high noise and vibration levels and with altered sleep and eating patterns. Indeed, there are reports suggesting that interpersonal conflict and depression may have contributed to early mission termination. Perhaps the most threatening factor to the health of individuals during extended travel in space is the significant elevation in ionizing radiation. For instance, the dose of ionizing radiation received during a 6-month stay on the International Space Station can be 15-fold greater than living 1 year in Houston, Texas. Depending on the type and dose of exposure, ionizing radiation can lead to damaged nerve cells in the central nervous system, cataracts, reduced fertility, and potential carcinogenic hazards. Hence, it is clearly a misconception to view space as a condition of reduced stress. The physiological responses to any one or a combination of the stressors associated with space missions can result in a loss in function and a subsequent compromise of health, particularly on return to a higher-gravity environment such as Earth.

Impact on Body Fluid and Electrolyte Balance

In the absence of gravity, altered hydrostatic pressure gradients within the cardiovascular system represent a potent stressor experienced immediately on exposure to space, resulting in a redistribution of body fluids that increases perfusion in the upper body regions while decreasing perfusion in the lower body regions. Increased filling of the heart and central circulation activate volume receptors that initiate an inhibition of vasopressin (a water-retaining hormone) and the renin-angiotensin-aldosterone system (a salt-retaining hormone response) that regulate body fluid and electrolyte balance. These neuroendocrine responses result in the increased excretion of water (diuresis) and sodium (natriuresis) from the kidneys. Although there may not be clinically significant alterations in electrolyte concentrations in the body fluids, plasma volume is reduced within 24–48 h of exposure to space. The resulting elevation in hematocrit (ratio of red blood cells to total blood volume)

inhibits the secretion of a hormone responsible for stimulating red blood cell production (erythropoietin) and subsequently induces a more gradual decrease in red blood cell mass. The result of kidney excretion of sodium chloride and reductions in plasma and red blood cell volumes is a resetting of the total circulating blood volume by 10–15% below the preflight level with little change in the primary electrolyte and protein concentrations in the body fluids.

Impact on Nutrition

In addition to the involuntary loss of body fluids and electrolytes, space alters dietary intake through changes in eating behaviors. The most prominent evidence that minimal nutritional requirements are compromised in space is a significant average reduction of approximately 7% (~4 kg) in body weight. However, the average nutritional composition of the typical diet during space missions is similar to that on Earth with ~16–18% protein, ~17–25% fat, ~60% carbohydrate, ~1% fiber, and ~3% minerals. Average daily fluid (>2000 ml) and sodium (>3500 mg) intakes are at or above recommended minimal requirements, whereas the average dietary calcium intake of approximately 900 mg day⁻¹ is below the recommended dietary allowance (RDA) of 1000–1200 mg day⁻¹. The average daily baseline energy expenditure in space has been estimated at 2500 kcal, although the actual daily energy expenditure is much often higher than this because of the performance of physical exercise and infrequent extravehicular (outside the spacecraft) work activities (EVA). When the data are standardized for body size (weight), it becomes clear that space inhibits hunger because there is a significant and consistent reduction in daily energy intake and a negative nitrogen balance. Reduced caloric intake (i.e., failure to consume available food) in space has been associated with crewmembers' decreased appetite, feeling of fullness in the abdomen, nausea, and preoccupations with critical mission tasks.

Impact on the Cardiovascular System

The loss of circulating blood volume contributes directly to a reduction in cardiac filling, as evidenced by the reduction in echocardiographic measures of end-diastolic (input) and stroke volumes (output) in astronauts following space flight. Despite compensatory elevations in heart rate, a subsequent reduction in cardiac output can result in low blood pressure (hypotension) if compensatory peripheral vasoconstriction is not adequate. In addition to reduced circulating vascular volume, there is evidence of

alterations in cardiovascular structures that occur during adaptation to space. Magnetic resonance imaging of cardiac muscle mass before and after space missions has revealed evidence of a smaller myocardial mass (cardiac atrophy), which could contribute to the reduced myocardial contractility and stroke volume that is observed when astronauts return to Earth from space. In the relative absence of gravity and posture-related hydrostatic pressure gradients, the space environment elicits much smaller fluctuations in pressures within the cardiovascular system than those that naturally occur during change in posture in the terrestrial gravity environment. Without the dynamic stimulation of the baroreceptors (pressure receptors) from such pressure fluctuations, space is associated with a compromise to reflexes that regulate blood pressure and flow (baroreflexes) only on return to Earth. There is also evidence of elevated sympathetic nerve activity and circulating catecholamines during exposure to the space environment. Higher sympathetic nerve activity in the presence of lower blood volume is associated with the elevated constriction of the arteries in the peripheral circulation, a condition that represents a lower capacity to maintain blood pressure during standing. The condition of less circulating blood volume can be exacerbated by an increased venous compliance of the lower extremities that can lead to a greater accumulation of blood away from the brain and heart and has also been reported following exposure to space.

There are at least two documented functional compromises to the health and safety of astronauts that are associated with these cardiovascular alterations during space. On return to Earth, some degree of cardiovascular instability due to the development of low arterial blood pressure during standing (orthostatic hypotension) has been reported in many individuals who have traveled in space. Significant orthostatic hypotension has been described in 40–50% of crew members in the U.S. space program and is associated with symptoms such as dizziness, lightheadedness, and blurred vision. In some astronauts, this condition has led to fainting (syncope) and is defined as orthostatic intolerance. Orthostatic hypotension and intolerance after return from space are associated with reduced cardiac output, which is associated with low circulating blood volume, which is further complicated by the increased pooling of blood in the lower extremities due to increased venous compliance (extension of the veins) and attenuated elevation in heart rate due to cardiac baroreflex impairment. Compromised orthostatic performance in astronauts is of particular operational interest because of its potential to increase the risk of serious injury from falling, particularly during critical times such as an

emergency egress from the spacecraft. This potential risk has raised great concern and, subsequently, led to vigorous research to counteract the problem with various countermeasures.

On return from space, astronauts experience more than a 20% reduction in their maximal oxygen uptake (VO_2max ; aerobic capacity). The measurement of VO_2max provides an integrated index of the functional integrity of the cardiorespiratory system and its mechanisms that regulate the delivery to and use of oxygen by the working muscles. The reduction in VO_2max on return to Earth can be explained entirely by a decrease in cardiac filling and stroke volume associated with lower circulating blood volume. The cardiovascular effect of the reduction in VO_2max on return to Earth is highlighted if physical work is performed in the upright (i.e., orthostatic) posture, as evidenced by higher heart rates and lower stroke volumes measured in astronauts who exercise in the upright compared to the supine posture after their return from space. The operational consequence of reduced aerobic reserve is an increased stress on the cardiovascular system with any physical effort during or after return from a space mission. Although there is no documented case of an adverse cardiac event on return to Earth after a space mission, a potential health consequence of increased stress on the heart, particularly during intense exercise or physical work, could manifest itself in myocardial ischemia or abnormal cardiac rhythms.

Impact on Thermoregulation

On Earth, the body core temperature fluctuates within $\pm 0.5^\circ\text{C}$ as a consequence of circadian rhythm, with higher temperatures during the day than the night. Body temperature circadian rhythm is altered in space such that the minimum night temperature is elevated by 0.2°C and the maximal daily temperature is reduced by 0.2°C . Despite a change in the natural light–dark cycles to 90 minutes, the change in body temperature is in part a direct effect of low gravity because body temperature circadian rhythm can be altered by changes in gravity in the presence of normal light–dark cycles. While in space, the average sweat rate is 10% less and insensible water exchange is lower during the performance of physical work because convective heat flow and sweat dripage are reduced in the low-gravity environment by the formation of an observed sweat film on the skin surface. This results in high levels of sustained skin wetness that acts to suppress sweating. Consequently, the average sweat rate during exercise is 10% less in space and crew members demonstrate a faster rise in body core temperature for a given absolute level of

physical work after return from space. After return to Earth, skin blood flow is reduced at rest (probably associated with elevated sympathetic vasoconstriction) and the sensitivity of active vasodilation and sweating are impaired during exercise. Although there are few measurements of body temperatures recorded on astronauts during their daily activities in space, recorded alterations in the response to body temperature during daily exercise suggest a change in thermoregulation that could compromise the capacity for heat exchange and lead to higher thermal loads during EVA. The functional consequence of alterations in thermoregulation following space flight is an impaired ability to dissipate body heat during physical work, with a higher risk of heat injury.

Impact on the Skeletal Muscle System

A significant stress associated with the relative absence of gravity in space is the unloading and subsequent disuse atrophy of skeletal muscles, especially those of the lower extremities. The magnitude of the resulting decrease in limb circumference has been used as a gross index of muscle atrophy. In addition, muscle biopsies taken from astronauts before and after space missions have revealed significant muscle atrophy as evidenced by reduction in cross-sectional areas (CSAs) of slow-twitch and fast-twitch muscle fibers of the vastus lateralis (a quadriceps muscle). The relative reduction in muscle fiber CSAs is approximately 50–60% greater in larger fast-twitch fibers, which are associated with force development (i.e., strength), than in smaller slow-twitch fibers, which are associated with posture and endurance. Muscle atrophy in space is also accompanied by reduced capillary-to-fiber ratio in both slow- and fast-twitch fibers after flight, a condition that can contribute to lower oxygen delivery and use and the cardiovascular effects of limiting $\text{VO}_{2\text{max}}$.

In addition to changes in muscle morphology, space-flight causes histochemical alterations. Although there are no significant changes in anaerobic (glycolytic) enzyme activities in muscles following space flight, the activities of enzymes associated with aerobic metabolic pathways (succinate dehydrogenase, citrate synthase, β -hydroxyacyl-CoA dehydrogenase) and the use of oxygen are reduced in both slow- and fast-twitch muscle fibers. Thus, prolonged muscle unloading and reduced energy requirements associated with space causes muscle atrophy with subsequent compromises in the capacity to generate force and in the delivery and utilization of oxygen at the level of muscle fibers.

The alterations in cellular morphology and histochemistry of skeletal muscle resulting from space

travel are associated with detriments in function. Muscle strength can be decreased by 20% for knee extensors and 10% for knee flexors. In addition to the loss in muscle strength, an increase in muscle fatigue is evidenced by a 50% increase in motor nerve activity (i.e., amplitude of electromyographic recordings) required to develop an equal force in calf skeletal muscles following a space mission compared with preflight measures.

The reductions in the ability to develop and maintain dynamic muscle forces that are required for normal daily functions on Earth represents a clinical consequence of muscle atrophy associated with space. For instance, a 10% decrease in force generation in the muscle groups of the lower extremities associated with adaptation to space is associated with a 10–15% reduction in distances of long and high jumps. The atrophy and fatigue of postural muscles can limit the ability to function during simple standing. The significant loss of muscle structure and function could predispose individuals to serious injury during physical activities or render them incapable of performing routine tasks required for normal living such as standing, stair climbing, and getting out of bed.

Impact on the Skeletal System

The result of the space environment on the integrity of the skeletal structure is clear; bone mass and bone mineral density (BMD) decrease in space. The most profound cause of bone loss in space is the dramatic unloading of bone with the relative absence of gravitational forces and dynamic mechanical forces exerted by skeletal muscles during movement on Earth. Bone loss begins immediately on unloading and is associated with a rapid and sustained loss of calcium from the body. The state of the skeletal system is dictated by bone mass turnover, which is determined by the net balance between resorption and formation. Bone resorption increases within the first few days of space, with an overall increase in bone resorption of 50% during long-duration flights, as indicated by elevated urinary calcium excretion. Although not all data support the notion of changes in bone formation in space, there exists some biochemical evidence that suggests a possible reduction in bone formation such as slight reductions in osteocalcin and bone-specific alkaline phosphatase. Thus, it appears that bone loss in space is due to increased bone resorption compounded by a slowly developing decrease in bone formation. Bone calcium can be lost at rates of up to 140 mg day^{-1} during flight. During 4–14 months in space, whole body BMD decreases at a rate of approximately 0.6% per

month despite the implementation of physical exercise countermeasures of $1\text{--}2\text{ h day}^{-1}$.

In addition to the unloading of bone with the absence of gravitational forces and dynamic mechanical forces exerted by skeletal muscles, other characteristics of the space environment are not conducive to the maintenance of a healthy skeletal structure. The near abolishment of ultraviolet light within the spacecraft environment can contribute to the reported reduction in vitamin D required for normal bone formation and breakdown (resorption), leading to the inhibition of calcium absorption in the intestine, parathyroid hormone release, and mineralization of bone. Ambient CO_2 levels, which are normally 0.03% on Earth, are chronically elevated to approximately 0.4% inside the spacecraft during nominal crew activity, with peaks of 1–3% during physical exercise workouts or visits from additional crew members. These high ambient CO_2 levels in the spacecraft can result in a more acid state within the body tissues, requiring bone resorption (bone breakdown at the expense of maintaining bone density) to provide bases such as carbonates and phosphates to buffer the respiratory acidosis. Although not consistently reported in all astronauts, the psychological stress of space travel may also contribute to bone loss by the direct effect that increased cortisol (stress hormone) has on stimulating bone resorption. In addition, abnormal nutritional habits reported in some crew members, such as reduced energy and calcium intake and a high sodium diet, may also contribute to the increased bone loss in space.

Health risks associated with bone degradation in space have been proposed by some flight surgeons. The increased blood and urinary calcium concentrations can increase the risk of kidney stones. There are medical reports of the formation of kidney stones in space that have resulted in infection and discomfort that could threaten the success of a space mission. Because the qualitative changes in bone in space are similar to those reported in patients with disuse osteoporosis, an increased risk of bone fracture on return to Earth represents one of the greatest health concerns of long exposures to space.

Impact on Neurovestibular Function

Neurovestibular function is important for maintaining normal posture and balance on Earth. There are several anecdotal reports by astronauts that indicate significant impairment to neurovestibular function after returning from space. While driving a car on a curved ramp, one astronaut voluntarily pulled off the road because he was experiencing a strong feeling

of tilt. In another instance, an astronaut fell to the ground while attempting to walk across a room to his bed in the dark. The gravitational unloading of the vestibular system in space causes numerous adaptations that can compromise the postural stability of an individual on return to Earth. Astronauts with their eyes closed significantly overestimate the degree of tilt when placed in a chair that is rotated sideways or tilted in a roll direction after returning from space. Experiments following space flight clearly demonstrate that astronauts show the greatest postural instability when they must rely on vestibular rather than visual information to maintain posture. Because of its importance in normal daily functions such as walking, running, navigation, and driving a car, impaired neurovestibular function associated with adaptation to space may increase the risk of injury from accidents and falls following return to Earth. Fortunately, most data indicate rapid improvement in balance and posture within hours of returning to Earth.

Impact on the Immune System

There is strong evidence that humans who fly in space have compromised immune function. During the Apollo missions, 15 of 29 astronauts reported bacterial or viral infections either during flight or within the first week after returning to Earth. During the infamous Apollo 13 mission, Fred Haze suffered from a severe urinary tract infection. The examination of cell-mediated immune responses measured from blood samples drawn from various astronauts and cosmonauts after their return from space revealed a lower immune response as indicated by an inhibited mitogen-induced formation of leukocytes, a severe decrease in the ability of leukocytes to produce interferon- α/β , an altered leukocyte subset distribution and interferon production, and reduced natural killer cell activity. Although the cause(s) of compromised immune function in space is unclear, the stress associated with confined environments, intense work schedules, exposure to radiation, poor nutrition, sleep deprivation, and/or the absence of gravity have all been associated with immune suppression. In space, more frequent illnesses associated with bacterial or viral infections can compromise the successful completion of a space mission by reducing the capacity to perform physical work. When back on Earth, a significant risk to the health of a space traveler is that immune dysfunction might make the crew more susceptible to more chronic tissue radiation damage and to the future development of tumors and cancers.

Figure 1 Cascade diagram of the relationships between physical and physiological stresses associated with the space environment and alterations in physiological functions associated with compromised health status. BMD, bone mineral density; BP, blood pressure; HR, heart rate; NE, norepinephrine; Q, cardiac output; RBCs, red blood cells; SV, stroke volume; TPR, total peripheral resistance; UV, ultraviolet; Vit D, vitamin D; VO₂max, maximal oxygen uptake.

Summary

The reduction of gravity in space presents an environmental stress that has profound effects on the structure and function of virtually all human tissues, resulting in physiological responses often seen in conditions of compromised health associated with aging, deconditioning, or inactivity-related diseases. The cascade of physical, physiological, and psychological responses associated with exposure to space is complex and interactive (Figure 1).

Although the absence of gravity is probably the most significant cause of physiological adaptations in space, the confined environment of space travel with changes in light, ambient gases, ionizing radiation levels, bacterial growth, and diverse personalities living together in confined quarters for long periods of time in the presence of high noise and vibration levels, intense work schedules, and altered sleep and eating patterns can contribute to organ dysfunctions. The space environment presents numerous physical and chemical conditions that can have profound effects on physiological health, the most significant effects of which occur on return to Earth's gravity.

Bone and Joint Complications

Glossary

<i>Autonomic nervous system</i>	Part of the nervous system that regulates several vital functions through two mutually opposing systems, the sympathetic system and the parasympathetic system.
<i>Bradycardia</i>	A slow heart rate, usually less than 60 beats per minute in adults.
<i>Cauda equina</i>	A bundle of spinal nerve roots below the termination of the spinal cord at the first lumbar vertebra. Typically it is more resistant to injury than the cord itself.

Conus medullaris

The tapering terminal part of the spinal cord at the level of the first lumbar vertebra that contains the nerves that serve distal lower extremity function and sphincter control.

Detrusor

The muscle present in the bladder wall that contracts and pushes urine out during micturition.

Ileus

Loss of muscular contractions in the bowel wall causing atony and dilatation of bowel loops.

Osteomyelitis
Priapism

An infection of bone, usually bacterial.
Involuntary, persistent erection of the penis.

Spinal cord injuries are relatively uncommon and predominantly affect young males (80–85%). Overall, about 55% of injuries affect the cervical spine and 15% each affect the thoracic, thoracolumbar, and lumbosacral spine.

Apart from weakness, paralysis, and sensory changes, in the acute stage (depending on the level of injury) certain physiological changes are often evident. These include spinal shock, paradoxical respiration,

low body and high skin temperature, priapism, and a sweating level. Spinal shock is usually seen in injuries above the T6 level and is characterized by hypotension and bradycardia without hypovolemia due to loss of vascular sympathetic tone. The higher the level of injury and the more complete the injury, the greater the intensity and duration of spinal shock. The motor and sensory functions usually recover (if any recovery is possible) within hours, but the autonomic component of spinal shock (loss of sympathetic function) may persist for days to months. Paradoxical respiration is the result of diaphragmatic contraction in the face of intercostal muscle paralysis. The skin is warm because of a loss of sympathetically mediated peripheral vasoconstriction; this also causes the core temperature to fall. Priapism may result from an unopposed parasympathetic function, and sweating is lost because of loss of sympathetic activity.

Cardiovascular Complications

Cardiovascular complications are most common with complete injuries of the spinal cord in the cervical or high thoracic regions.

Hypovolemia and Hypotension

Spinal shock is a diagnosis of exclusion because spinal cord injury is often accompanied by other injuries. Extra emphasis should be placed on detection of any other injuries, as the lack of sensation and loss of abdominal muscle tone may make physical examination unreliable. Injuries to the chest, abdomen, pelvis, and long bones must be actively sought and excluded as a source of blood loss, hypovolemia, and hypotension. Hypovolemia and hypotension should be corrected rapidly. Hypotension in particular may increase the area of secondary injury in the spinal cord and worsen outcome. Crystalloids, colloids, and blood products may be used to replace volume as needed. Clinicians must be aware, however, that relatively low systolic blood pressure is normal in an acute high spinal cord injury, and the presence of otherwise normal cardiovascular function as indicated by adequate urinary output suggests that the patient is hemodynamically stable. Later in the course of the injury, hypotension may occur with upright posture. This is due to venous pooling and the lack of sympathetic output. It can be prevented by elastic stockings, abdominal binders, or small doses of vasopressors.

Bradycardia

Unopposed vagal activity with the loss of sympathetic activity causes bradycardia. It may be severe, especially in young patients with a high vagal tone.

Atropine or glycopyrrolate may be used to reverse bradycardia. If the patient is intubated, suctioning the endotracheal tube may sometimes provoke severe bradycardia.

Autonomic Hyperreflexia

Autonomic hyperreflexia is characterized by massive sympathetic outflow in response to certain noxious stimuli, usually genitourinary manipulations such as a change or irrigation of an indwelling Foley catheter. In severe cases, marked elevations in blood pressure, bradycardia, flushing, headache, nausea, and cardiovascular collapse may occur. There is severe vasoconstriction below the level of the cord injury and vasodilatation above it. This unopposed reflex sympathetic activity is usually seen well after the period of the spinal shock and is treated by withdrawing the initiating stimulus and administering vasodilators. Spinal anesthesia eliminates this reflex sympathetic outflow and should be considered for patients undergoing all major genitourinary procedures despite the patient's anatomic anesthesia below the injured level.

Venous Thrombosis

Immobilization and venous stasis, coagulation abnormalities, decreased fibrinolytic activity, and endothelial damage have been implicated in the high incidence of deep venous thrombosis in patients with complete spinal cord injury. Deep venous thrombosis usually occurs in the first 2 to 3 weeks after a spinal cord injury. A high index of suspicion is necessary, and prophylactic caval filters may be considered for high-risk patients.

Over the long term, cardiovascular function declines at an accelerated rate, and asymptomatic cardiovascular disease is also more prevalent in patients with spinal cord injury. This has been linked to the presence of dyslipidemia, enforced rest with limited exercise options, insulin resistance and hyperinsulinemia, and elevated percentages of body fat.

Respiratory Complications

Complete lesions above the C3 level are accompanied by a loss of diaphragmatic and intercostal muscle activity. These patients are dependent on artificial ventilation, initially through an endotracheal tube and later through a tracheostomy. Patients with mid-cervical lesions may require ventilatory assistance initially but can usually be ventilator-free long term. They remain at high risk for repeated pulmonary infections, requiring mechanical ventilation, however, due to lack of respiratory reserve. Patients with low cervical and high thoracic injuries have normal diaphragm

function but lack intercostals and abdominal muscle tone. Respiratory mechanics and efficiency are altered, as is the ability to breathe deeply or cough. Bronchial secretions are also increased because of the inability to clear airways; atelectasis, hypoxemia, and repeated infections are common.

Gastrointestinal Complications

In the acute stage of cervical or high thoracic spinal cord injury, gastric dilatation and ileus may be seen. These may persist for up to a week in complete cervical injuries. Abdominal distention, absence of bowel sounds, and abdominal x-rays showing dilated jejunal, ileal, and large bowel loops help make the diagnosis. Large volumes of fluids and electrolytes may be sequestered in the bowel and may need replacement. Cushing ulcers may also be seen in the gastrointestinal (GI) tract and may cause GI bleeding and bowel perforation. All spinal cord injury patients should receive prophylaxis with H₂ blockers or proton pump inhibitors. Long-term effects on the GI tract include gastro-esophageal reflux, delayed gastric emptying, altered colonic motility, and loss of control of defecation.

Urologic Complications

Initially after high spinal cord injury, during the period of spinal shock, the bladder is completely areflexic, but the sphincter tone may be high, necessitating a Foley catheter to allow for urinary drainage. After the period of spinal shock, detrusor contractions may return, but often these movements are not coordinated with the sphincter mechanisms, resulting in poor bladder emptying. Different patterns of incoordination may be seen with conus medullaris/cauda equina injuries. Urinary infections, especially with ureteral reflux, are major problems causing renal damage, and management is targeted to the avoidance of these. Clean intermittent catheterization remains the cornerstone of management.

Skin Complications

Pressure ulcerations are an area of breakdown leading to ischemia and necrosis of the skin. Prolonged

exposure to pressures just slightly above capillary filling pressure initiates a series of events leading to tissue necrosis and ulceration and is common in dependent areas such as the back and ischial tuberosities. Patients with spinal cord injury are also subject to venous stasis, atrophy of fat and muscle, moist perineum from fecal and urinary incontinence, and increased shearing stresses, which increase the risk of pressure ulceration. If left untreated there is invasion of deep fascia, muscles, bone, and joints. When this occurs, osteomyelitis is common and is a source of septicemia.

Bone and Joint Complications

Removal of weight bearing as a result of spinal cord injury results in skeletal adaptive responses characterized by loss of bone mineral and a negative calcium balance. This may be prevented by exercise therapy, electrical stimulation, and antiresorptive agents. An exercise regimen will also prevent joint contractures and maintain joint mobility.

Glossary

Anti-depressants

The pharmacological classification of drugs typically used to treat mood disorders; include serotonin reuptake inhibitors and tricyclics.

Cognitive-behavioral therapy

An approach to psychotherapy that employs a variety of techniques in an attempt to change behavior or mood by disputing negative or irrational cognitive thought processes and replacing them with more rational or positive thought processes.

Neuropsychological evaluation

An assessment that typically involves the administration of several standardized cognitive tests that are sensitive to the effects of brain dysfunction.

*Paralysis
Paraplegia
paralysis*

A complete or partial loss of function. The paralysis of the lower extremities as the result of an injury below the first thoracic vertebrae.

Posttraumatic stress disorder (PTSD)

An anxiety disorder that is characterized by the reexperiencing of an extremely traumatic event such as a natural disaster, war, or rape. This syndrome is often accompanied by increased arousal, recurrent thoughts or images, and avoidance of stimuli associated with the trauma.

*Premorbid personality characteristics
Quadriplegia*

The level of psychological or personality functioning before the onset of a disorder or condition.

The paralysis of all four extremities as the result of an injury above the thoracic vertebrae.

Spinal cord injury (SCI)

Trauma to the spinal cord from a sudden blow to the spine resulting in vertebral fractures and dislocations; can result in varying degrees of paraplegia and quadriplegia.

Spinal cord injury (SCI) is generally due to a sudden blow to the spine resulting in vertebral fractures and dislocations. This type of trauma can result in varying degrees of paraplegia (the paralysis of the lower extremities as the result of an injury below the first thoracic vertebrae) and quadriplegia (the paralysis of all four extremities caused by an injury above the thoracic vertebrae). Consequently, SCI victims may endure problems with breathing and bowel or bladder control. Vulnerability to secondary medical problems such as chronic pain, respiratory problems, heart failure, and decubitus ulcers are also very common among SCI patients.

Prevalence

There is an estimated 11 000 new cases of SCI reported each year in the United States, and in 2005, there were reportedly 250 000 Americans living with SCI. Motor vehicle accidents account for a majority of the injuries, followed by falls, acts of violence (e.g., gunshot wounds and assaults), and sport activities.

Young adult men are primarily affected by SCIs; however, the rates are increasing among women. A 1998 study conducted by Schackelford, Farley, and Vines comparing men and women with SCI found that approximately 82% of SCIs occur in men compared to a 20% occurrence rate in women. The prevalence of SCIs also appears higher in Whites (62.9%), followed by African Americans (22%) and Hispanics (12.6%). The life expectancy rate for SCI patients has steadily increased during the past 50 years, primarily as a result of advanced medical care and the presence of emergency rehabilitation services. Approximately 85% of SCI patients go on to live 10 years or more if they survive the first 24 h after their injury. Recent statistics indicate that the average age of people living with SCI is 40 years. Because SCI is a lifelong disability, the need for health-care services will continue to grow as patients with SCI live longer.

Psychological Effects of Spinal Cord Injury

In addition to secondary medical complications, many SCI patients also experience emotional problems such as depression, anxiety, and social isolation. Psychological distress may stem from diminished independence, functional impairment, chronic pain, and loss of social and work status. Depression is thought to be the most common psychological disorder among SCI

patients. A review of the literature suggests that depression rates among SCI patients vary, with a majority of the reports indicating that between 20 and 45% of people with SCI suffer from depression. Individuals with a history of psychological disorders and substance use may be at increased risk of experiencing depression following SCI.

People with SCI appear to be at greater risk for developing anxiety disorders compared to the general population. Scivoletto et al. found in 1997 that SCI patients who presented with greater medical needs were often more anxious and depressed than SCI patients with less severe medical problems. High levels of psychological distress were also indicated for SCI patients who lived alone, had lower levels of education, and were unemployed. Individuals with a disability (e.g., polio or SCI) were also found to report lower levels of life satisfaction compared to nondisabled people. In a 1999 study examining the correlates of stress in a sample of 187 SCI patients, Gerhart and colleagues found that depressive symptoms, poor perceived well-being and poor life satisfaction were strongly associated with earlier and future stress. Interestingly, medical conditions such as pressure sores and upper-extremity pain were not found to be associated with stress in this sample.

Because SCI is often the result of a traumatic and life-threatening accident, patients with SCI may also suffer from posttraumatic stress disorder (PTSD). Radnitz et al. reported a PTSD prevalence rate of 10–15% among SCI patients, whereas other researchers reported rates up to 40%. Interestingly, Radnitz and colleagues concluded that individuals with quadriplegia were diagnosed with PTSD less frequently than individuals with paraplegia, therefore suggesting that there may be an increased vulnerability for PTSD among paraplegic SCI patients. According to the researchers, the aforementioned finding may reflect the fact that quadriplegia involves injury to the upper region of the spinal cord, thereby damaging the nerve fibers that affect sympathetic arousal thought to be associated with PTSD. In a 2003 study that attempted to identify the risk factors of PTSD in SCI patients, Nielsen did not find significant relationships between level of paralysis and PTSD or trauma etiology and PTSD. However, when considering demographic variables, the author found that marriage was associated with a decreased likelihood of SCI patients developing PTSD.

There is a high risk of pre-injury substance abuse among SCI patients compared to the general population. Many patients undergo some sort of substance abuse counseling as part of a postinjury rehabilitation program; however, this does not always prevent patients from returning to substance use following hospital discharge. In addition, one 2004 study

found that substance use at the time of injury was related to a negative response to problem solving in SCI patients. SCI patients are often prescribed narcotic and analgesic medication to treat chronic pain, and unfortunately, the potential for abuse of prescription drugs by some SCI patients is high. In a study examining alcohol and marijuana abuse in a sample of 123 SCI patients, it was found that patients who abused alcohol perceived their health status to be poorer, were more clinically depressed, and experienced more stress in their lives than patients with no alcohol abuse. Marijuana users also reported higher levels of stress and depression.

Suicide rates among SCI patients are five times higher than among nondisabled people, and suicide is the leading cause of death in the SCI population. Pre-injury personality characteristics, inadequate coping skills, history of substance abuse, and a poor social network have been identified in the literature as risk factors for suicidal ideation in patients with SCI. Young, adult, White males appear to have the highest rate of suicide within the SCI population. It is not surprising that most SCI patients exhibiting suicidality meet diagnostic criteria for depressive disorders. Kishi et al. examined acute-onset suicidal ideation and delayed-onset suicidal ideation in a group of SCI patients as well as patients suffering from stroke, brain injury, or myocardial infarction. Compared to patients who were identified as having delayed-onset suicidal ideation, patients with acute-onset suicidal ideation exhibited greater risk factors, including a history of psychological problems and substance abuse as well as poor social support. Therefore, it is possible that suicide rates could be significantly reduced if patients at risk are identified early in rehabilitation programs.

Psychological Assessment of Patients with Spinal Cord Injury

A comprehensive evaluation, including a thorough assessment of personality, substance use, and emotional and cognitive functioning, should be conducted for patients with acute SCI. With respect to personality testing, it may be important to identify characteristics that may interfere with rehabilitation and those individuals at risk for developing significant emotional difficulties following SCI. Chronic pain has been associated with depression and negatively affects coping. Therefore, assessing pain in SCI patients should also be an important component to the postinjury psychological evaluation. Pain could also negatively impact the rehabilitation process, especially if uncontrolled or untreated. The presence of chronic pain can also lead some patients to self-medicate with alcohol or illicit drugs. Because people

with SCI are often prescribed narcotics for pain relief, the potential of abusing prescription drugs is often present, thereby requiring physicians and mental health providers to routinely assess for improper use of prescription drugs.

A majority of SCI patients often have an underlying head injury and demonstrate poor performance on neuropsychological tests. A brain injury can be associated with lingering neurocognitive and neurobehavioral sequelae that can negatively impact rehabilitation. Therefore, following SCI, patients may need to undergo at least a brief assessment of cognitive functioning. Patients exhibiting significant cognitive difficulties on brief assessment or patients with any known brain injury should be referred for a more comprehensive cognitive evaluation, preferably by a neuropsychologist. A neuropsychological evaluation may provide additional information regarding the patient's cognitive strengths and weaknesses that can aid in determining prognosis for rehabilitation. Schmitt and Elliott found that SCI patients with higher verbal learning skills reported greater levels of self-adjustment and acceptance of their injury. A neurocognitive evaluation may also aid in determining what academic or work accommodations need to be implemented should the patient be able to resume school instruction or employment.

Treatment of Emotional Distress in Spinal Cord Injury Patients

Psychological services should be available for injured individuals and their families while the patients are in the hospital and following discharge. Psychotherapeutic intervention should focus on adjustment, self management, and skills training. Several studies conducted by Craig and colleagues have shown that employing cognitive-behavioral strategies as a form of treatment for SCI patients with significant levels of depression and anxiety are effective. Cognitive-behavioral therapy attempts to change behavior or mood by disputing negative or irrational cognitive thought processes and replacing cognitive distortions with more rational or positive thought processes. Cognitive-behavioral techniques are not only beneficial in the treatment of mood disorders, but have also been suggested efficacious for managing pain. Overall, cognitive-behavioral therapy may be potentially cost effective by decreasing the number of hospital readmissions and drug use.

In addition to individual psychotherapeutic intervention, group therapy may also be a valuable form of treatment for SCI patients, especially in a hospital setting. Groups that are psychoeducational in nature and focus on specific themes, such as coping with the injury, vocational issues, sexual dysfunction,

substance abuse, or secondary medical complications may be of great benefit to acutely injured patients. Therapists might also consider inviting family members to attend a separate support group to address the emotional, logistical, and financial issues associated with having a family member with SCI.

Issues related to sexual functioning in the SCI population is becoming more recognized and discussed throughout SCI literature. Of course, the level of physical impairment or paralysis following SCI can affect sexual functioning. Psychotherapeutic intervention that addresses both adaptation and coping with the physical and functional changes in sexuality following SCI is necessary. Erectile dysfunctions in men and physiological changes in women are common features of SCI. Obviously, people with SCI are not immune to or incapable of acquiring sexually transmitted diseases (STDs), and women with SCI may become pregnant. Therefore, mental health providers may also find themselves in a position to educate SCI patients on safe sex practices.

Pharmacological treatment may also be advantageous for the treatment of emotional disorders (e.g., depression and anxiety) in patients with SCI. Because they have fewer side effects compared to tricyclic antidepressants, serotonin reuptake inhibitors (SSRIs) usually have a more benign side-effect profile. However, few studies have been conducted that demonstrate the efficacy and possible side effects of antidepressant therapy in SCI patients.

Life Satisfaction and Coping with Injury

Factors such as premorbid personality characteristics and available social support can strongly influence coping with SCI. Frank and Elliott found that patients who believed they had some control over their situation and events experienced less depression and were better adjusted than patients who believed they had little control over their life situation and health status. Other protective factors against depression and anxiety appear to be age and the number of years since the injury occurred.

Life satisfaction has been shown to be higher in SCI patients with adequate social support than in SCI patients with poor social support systems. Length of time living with SCI was also positively correlated with greater life satisfaction. Similarly, a 2002 study found that social support was associated with lower levels of hopelessness and depression. Ongoing health-care services are also necessary because the life span of individuals with SCI continues to rise, thereby increasing the probability of secondary medical conditions. One study found that SCI patients who received regular follow-up medical care reported better health, independence, and fewer

severe secondary medical complications, and demonstrated lower depression scores than SCI patients who did not receive follow-up care. In essence, adequate health care delivered by well-trained physicians, nurses, mental health-care providers, vocational rehabilitation specialists, and other essential staff is pertinent in order to help facilitate a longer life expectancy and increased quality of life among SCI survivors.

Other Startle Phenomena

Glossary

Amygdala

A bilateral limbic structure located just anterior to the ventral tip of the hippocampus. The amygdala is a collection of perhaps 13 different nuclei, including the central nucleus of the amygdala, the basolateral amygdala nucleus, and the lateral amygdala nucleus. This structure is critically involved in fear as well as attention, aggression, sexual behavior, and certain aspects of appetitive behavior, such as secondary reinforcement.

Bed nucleus of the stria terminalis (BNST)

A structure surrounding the anterior commissure that is related anatomically and functionally to the amygdala. It is also believed to play a role in fear or anxiety as well as sexual arousal.

Corticotropin releasing hormone (CRH)

A 41-amino-acid peptide that coordinates the behavioral, endocrine, and autonomic indices of the mammalian stress response by acting as a neurohormone and neurotransmitter (neuromodulator) in the brain. CRH and its receptors are expressed in both the amygdaloid nuclei and the BNST.

Nucleus reticularis caudalis pontis

A group of large neurons in the pontine reticular formation that forms the final nucleus in the brain stem involved in the primary acoustic startle circuit.

The mammalian startle response consists of a rapid extension and then flexion of a series of muscles in response to an abrupt stimulus that is usually auditory but may be somatosensory, vestibular, or visual. As a simple, stimulus-controlled behavior, the mammalian startle response has been used to investigate the neuroanatomical and cellular basis for learning and behavior.

Characterization of the Startle Response

Acoustic Startle

The acoustic startle reflex (ASR) typically is elicited by a brief auditory stimulus (90–120 dB, 50 ms duration). The minimum stimulus required to elicit a response in normal rats is approximately 80–90 dB, provided that the stimulus reaches full intensity within approximately 12 ms of the stimulus onset. Even very intense auditory stimuli do not elicit a startle reflex if they have long rise times (e.g., >25 ms). In mammals, the amplitude of the startle response is proportional to the duration of the stimulus (up to 8 ms) with a direct positive relationship between startle amplitude and stimulus intensity. In rodents, high-frequency auditory stimuli are more effective than low-frequency stimuli in eliciting startle. The startle reflex has been observed in every mammal tested and is characterized by an extremely short latency. In rats, electromyographic (EMG) recordings in hindlimb muscles indicate a response latency of 8 ms following onset of an auditory stimulus.

Air Puff Startle

The startle reflex can also be elicited by an air puff that contains both tactile and acoustic components. Across laboratories, the duration of the air puff stimulus ranges from 100 to 120 ms and the stimulus intensity ranges from 9 to 75 psi. Studies in hearing-impaired rodents have shown that the auditory component of a low-intensity air puff stimuli (12.5 psi) is primarily responsible for eliciting the startle response. With more intense air puff stimuli, the auditory and tactile stimuli synergize to produce large-amplitude startle responses. Air puff startle has been used not only to elicit and measure the startle reflex, but also as an unconditioned stressor. For example, in rats, air puff stimuli can induce ultrasonic vocalizations, activate the hypothalamic-pituitary-adrenal (HPA) axis, and increase defensive withdrawal responses.

Human Startle

In humans, startle involves primarily a flexion response that is most pronounced in the upper half of the body, particularly the face, neck, and shoulders, with the minimum response being flexion of the sternocleidomastoid muscle (a latency of 14 ms). The response begins with blinking of the eyes (a latency of 35 ms) and extends caudally, causing forward head movement, facial grimacing with widening of the mouth and occasional baring of the teeth, elevation

of the shoulders, abduction of the arms, bending of the elbows, pronation of the forearms, flexion of the fingers and trunk, abdominal contraction, and knee flexion. Thus, the human startle response primarily involves flexor muscles, but may also include extensors, depending on the subject's posture at the time of stimulus onset. Startle in humans is almost always measured via the amplitude of the eyeblink, which is highly graded in magnitude and shows the same types of plasticity as the whole body response in rodents.

Rodent Startle

In rodents, startle can result in prominent extension of the forelimbs and hindlimbs to the point where all four feet come off the ground. Smaller startle responses involve flexion of the back so that the body shortens and rises into a characteristic hunched posture. In both cases, startle amplitude is measured as a downward movement of a cage that is detected by transducers sensitive to rapid movement that put out a voltage proportional to the magnitude of the startle reflex (e.g., accelerometers, piezoelectric disks, load cells, and phonograph cartridges). Startle amplitude is typically defined as the maximal transducer output during a brief period of time (e.g., 200 ms) after onset of the eliciting stimulus. By sampling cage output over brief periods of time, startle can be readily discriminated from spontaneous or drug-induced changes in locomotor or stereotyped behavior.

Mediation of the Startle Reflex

Anatomical Structures

Because the ASR has such a short latency, a simple neural pathway must mediate it. In 1982, it was proposed that acoustic startle in the rat was mediated by four synapses: three in the brain stem (the ventral cochlear nucleus, an area just medial and ventral to the ventral nucleus of the lateral lemniscus, and the nucleus reticularis pontis caudalis) and one on to motoneurons in the spinal cord. Electrolytic lesions of these nuclei eliminated acoustic startle, whereas single-pulse electrical stimulation of these nuclei elicited startlelike responses with a progressively shorter latency as the electrode was moved farther down the startle pathway. However, it has now been found that the selective destruction of cell bodies without a concomitant loss of fibers of passage in the ventral nucleus of the lateral lemniscus or the area just ventral and medial to it did not eliminate startle, whereas comparable lesions in the nucleus reticularis pontis caudalis still completely eliminated startle. These data strongly suggested, therefore, that an additional synapse in the ventral nucleus of the lateral lemniscus or the area just ventral and medial might not be necessary for

relaying auditory information from the cochlear nucleus to the pontine reticular formation. However, all data still pointed to the critical importance of the nucleus reticularis pontis caudalis in the acoustic startle reflex. Until very recently, it has been unclear how auditory information gets to this traditionally non-auditory part of the brain stem. It is now known that in both rodents and humans there is a small group of very large cells (35 μm in diameter) embedded in the cochlear nerve, called cochlear root neurons. These neurons receive direct input from the spiral ganglion cells in the cochlea, making them the first acoustic neurons in the central nervous system. They send exceedingly thick axons (sometimes as wide as 7 μm) through the trapezoid body, at the very base of the brain, directly to an area just medial and ventral to the lateral lemniscus and continue on up to the deep layers of the superior colliculus. However, they give off thick axon collaterals that terminate directly in the nucleus reticularis pontis caudalis, exactly at the level known to be critical for the acoustic startle reflex. Most important, the chemical destruction of these cochlear root neurons completely eliminates the acoustic startle reflex. Although damage to the auditory root, where the cochlear root neurons reside, has not been fully ruled out, other tests indicated that these animals could clearly orient to auditory stimuli (e.g., suppression of licking) and had normal compound action potentials recorded from the cochlear nucleus.

Although there is still some disagreement, the acoustic startle pathway may consist of only three synapses on to the (1) cochlear root neurons, (2) neurons in the nucleus reticularis pontis caudalis, and (3) motoneurons in the facial motor nucleus (pinna reflex and perhaps the eyeblink) or spinal cord (whole-body startle; [Figure 1](#)).

In humans, the obicularis oculi muscles that are innervated by the facial motor nucleus mediate the eyeblink component of startle. Because the facial motor nucleus receives a direct projection from the nucleus reticularis pontis caudalis, the eyeblink component of startle could involve a pathway consisting of cochlear root neurons, the nucleus reticularis pontis caudalis, and the facial motor nucleus. However, this simple neural pathway may not be able to account for the relatively long latency of the eyeblink reflex (35 ms), so other pathways have been suggested.

Neurotransmitters that Mediate the Startle Reflex

Auditory nerve to cochlear root neuron synapse At the present time, there are no direct data on the identity of the neurotransmitter that may mediate startle at this level. Preliminary experiments in rodents suggest it may be glutamate acting on non-*N*-methyl-D-aspartate (NMDA) receptors because a local infusion

Figure 1 Schematic diagram of a primary acoustic startle pathway. Auditory nerve fibers synapse onto cochlear root neurons embedded in the auditory nerve. Axons from these cells project through the ventral acoustic stria and send projections to the nucleus reticularis pontis caudalis (PnC). Projections of cells in the PnC form the reticulospinal tract, which make monosynaptic and polysynaptic synapses in the spinal cord. These cells also project to the facial motor nucleus in areas critical for the pinna component of startle in rats and perhaps the eyeblink component of startle in humans (not shown). Lesions of the cochlear root neurons, the ventral acoustic stria, the PnC, or reticulospinal tract eliminate the acoustic startle response.

of the non-NMDA antagonist CNQX in the vicinity of the root neurons depressed startle, whereas local infusion of the NMDA antagonist AP5 did not.

Cochlear root neuron to reticulospinal neuron synapse
Glutamate acting on both NMDA and non-NMDA receptors may well be the neurotransmitter that mediates startle at the level of the nucleus reticularis pontis caudalis. Local infusion of either CNQX or

AP5 in rats chronically implanted with bilateral canulas aimed at the nucleus reticularis pontis caudalis significantly reduced startle amplitude by as much as 70–80%. AP5 and CNQX attenuated startle over a dose range, which indicated that the nucleus reticularis pontis caudalis is extremely sensitive to these compounds. Thus, small changes in neurotransmitter activity in this area may have a profound effect on the expression of the acoustic startle reflex.

Reticulospinal neurons to motor neuron synapse

Intrathecal infusion (into the subarachnoid space of the spinal cord to allow drugs to diffuse in the vicinity of motoneurons) of the non-NMDA antagonist CNQX or the NMDA antagonist AP5 each reduced the amplitude of the whole-body startle reflex in a dose-dependent manner. When EMG activity in the hindlimbs was used to define startle, intrathecal administration of a combination of AP5 and CNQX completely eliminated all EMG components of the startle response, consistent with the hypothesis that excitatory amino acids actually mediate startle at the spinal level. Moreover, when the EMG components of the startle reflex were separated into early or late components, CNQX preferentially eliminated the early components (a mean latency of 8.29 ms), whereas AP5 preferentially eliminated the later components (a mean latency of 14.57 ms or longer).

The fact that startle appears to involve both non-NMDA and NMDA receptors at the spinal level can be interpreted in a number of ways. The simplest possibility is that glutamate is released from reticulospinal tract terminals, which form monosynaptic connections onto motoneurons expressing both NMDA and non-NMDA receptors. The short-latency EMG components then reflect the activation of non-NMDA receptors, whereas the longer-latency EMG components reflect the activation of NMDA receptors. A second possibility is that reticulospinal neurons make both monosynaptic and polysynaptic connections via interneurons onto spinal motoneurons. The short-latency EMG components then reflect the monosynaptic connections on to non-NMDA receptors, whereas the longer-latency EMG components reflect polysynaptic connections involving NMDA receptors. A third possibility is that the short-latency EMG components of startle reflect the activation of non-NMDA receptors by the short-latency startle pathway described previously, whereas the later components reflect activity in other brain-stem structures, which then eventually activate NMDA receptors on spinal motoneurons. This idea can be tested by the direct stimulation of reticulospinal neurons in conjunction with intrathecal infusion of excitatory amino acid antagonists.

In summary, the excitatory amino acid glutamate may well mediate startle at each of the three central synapses along the acoustic startle pathway. NMDA and non-NMDA receptors appear to be involved at both the spinal cord and nucleus reticularis pontis caudalis. Processes involved in the release of glutamate, as well as changes in the sensitivity of glutamate receptors, are expected to affect startle and startle plasticity.

Modulation of the Startle Reflex By Stress

The Fear-Potentiated Startle Effect

In rats, the amplitude of the startle reflex is increased when elicited by an auditory stimulus shortly after the onset of a light paired previously with a foot shock. This fear-potentiated startle effect occurs only following prior light–shock pairings and not when lights and shocks have been presented in an unpaired or random relationship, indicating its dependence on prior Pavlovian fear conditioning. It is probable that the light produces a state of fear, which increases reflexive behavior, because drugs such as buspirone or valium, which

reduce fear and anxiety in humans, block the increase in startle in the presence of the light but do not systematically alter startle in the absence of light when appropriate doses are used. When the eyeblink component of the startle reflex is measured in humans, fear-potentiated startle can be produced using very similar conditioning procedures to those used in rodents. Humans also show an increase in startle amplitude simply when they are told that a shock might occur after presentation of a light or when they see threatening pictures such as a gun or an attacking dog. Conversely, pleasant pictures shown to humans or a light paired with food shown to rats reduce startle amplitude.

Figure 2 summarizes our knowledge of the neural pathways involved in the fear-potentiated startle effect using a visual conditioned stimulus. Visual information goes through the visual thalamus to the perirhinal cortex, which then projects to the amygdala, which has a direct projection to the nucleus reticularis pontis caudalis in the startle pathway. The lateral posterior nucleus of the thalamus, which receives heavy input from the retina, projects directly to the perirhinal cortex. Lesions of the lateral posterior nucleus of the thalamus, combined with lesions of the dorsal and ventral nuclei of the lateral geniculate, completely block

Figure 2 Working hypothesis of the neural pathways involved in fear-potentiated startle using a visual-conditioned stimulus and a foot shock-unconditioned stimulus. Visual information from the retina goes in parallel to the dorsal lateral geniculate nucleus and the lateral posterior nucleus in the thalamus. Lesions of both of these nuclei together after light–shock pairings eliminate fear-potentiated startle to a light. Lesions of either area alone or lesions of the visual cortex alone, which receive inputs from the dorsolateral geniculate nucleus, do not block the expression of fear-potentiated startle to a light. The lateral posterior nucleus projects directly to the perirhinal cortex, whereas the dorsolateral nucleus projects to the perirhinal cortex indirectly via the visual cortex. The perirhinal cortex projects to lateral and basolateral nuclei of the amygdala, which project to the central nucleus. The central nucleus has direct projections to the nucleus reticularis pontis caudalis, an obligatory part of the acoustic startle pathway; however, indirect projections via a synapse in the rostral midbrain probably are involved as well. Shock information is relayed to the lateral and basolateral amygdala via parallel inputs arising from the insular cortex and posterior thalamic nucleus. Lesions of both these areas together prior to light–shock training block the acquisition of fear-potentiated startle. However, lesions of both of these areas following training have no effect. Lesions of either area alone fail to block acquisition or expression of fear-potentiated startle. CRN, cochlear root neurons; CS, conditioned stimulus; PnC, nucleus reticularis pontis caudalis; US, unconditioned stimulus.

fear-potentiated startle using a visual-conditioned (but not an auditory-conditioned) stimulus. Lesions of either structure alone have no effect. Furthermore, posttraining lesions of the visual cortex, to which the dorsal nucleus of the lateral geniculate projects, do not affect fear-potentiated startle. Hence, visual information gets to the perirhinal cortex either directly from the lateral posterior nucleus or indirectly from the dorsal nucleus of the lateral geniculate via the visual cortex. Lesion data suggest that either one of these pathways is sufficient to mediate fear-potentiated startle using a visual-conditioned stimulus. The perirhinal cortex has heavy reciprocal projections with the lateral and/or basolateral nuclei of the amygdala. Relatively small lesions of the perirhinal cortex completely block fear-potentiated startle, provided the lesion includes an area of perirhinal cortex both dorsal and ventral to the rhinal sulcus.

Selective destruction of cell bodies in the lateral and basolateral nuclei of the amygdala completely block fear-potentiated startle using either a visual- or an auditory-conditioned stimulus when the lesions were made either before or after training. Lesions of the central nucleus (CeA), innervated by the basolateral nucleus of the amygdala, block the expression of fear-potentiated startle using either a visual- or an auditory-conditioned stimulus. The CeA has both direct and indirect projections via the central gray to the nucleus reticularis pontis caudalis, and lesions at several points along this pathway block the expression of fear-potentiated startle.

When shock is paired with light during fear-potentiated startle training, shock information is relayed to the basolateral amygdala via two parallel pathways. These include the caudal granular/dysgranular insular cortex and the posterior intralaminar nuclei of the thalamus. Pretraining lesions of both of these areas together, but not either one alone, blocked the acquisition of fear-potentiated startle. However, posttraining combined lesions of these same brain areas did not prevent the expression of conditioned fear.

Sensitization of Startle by Foot Shocks

When rats are presented with a series of startle stimuli before and after a series of 10 foot shocks presented at a 10-s interstimulus interval, startle shows a progressive increase in amplitude that peaks in approximately 10 min. The magnitude of this startle sensitization effect is directly related to the number or intensity of intervening shocks. Moreover, shocks given prior to presenting any startle stimuli also lead to an elevation of startle, indicating that enhanced startle results from sensitization rather than simply from

dishabituation. Like fear-potentiated startle, lesions of the amygdala block the shock sensitization of startle.

Noise-Enhanced Startle

The startle reflex is increased when elicited in the presence of steady background noise as well as following a period of sustained high-level noise. Although this may reflect an effect of noise stress, noise-enhanced startle is not blocked by lesions of the amygdala and shows inconsistent sensitivity to anxiolytic compounds.

Light-Enhanced Startle

When the startle reflex is elicited by a loud sound 5–20 min after a bright light has been turned on, there is an increase in the startle reflex. This effect is also decreased significantly by drugs that reduce anxiety in humans and may indicate an unconditioned anxiogenic effect of bright light that enhances startle. Humans show a significant increase of startle amplitude (i.e., of the eyeblink response) in the dark. The species difference may reflect fear of the light in a nocturnal species (rats) compared to fear of the dark in a diurnal species (humans). When the lights go off, many people feel more anxious, especially if they were afraid of the dark when they were young. In patients with posttraumatic stress disorder, startle is increased in the dark to a greater degree than that seen in combat controls. These individuals report that the darkness makes them think of being back at their guard post in Vietnam and anxious about being hit by an incoming mortar.

Like fear-potentiated startle, local infusion of the glutamate antagonist NBQX into the basolateral nucleus of the amygdala blocks light-enhanced startle. However, unlike fear-potentiated startle, NBQX infused into the BNST, but not the CeA, blocks light-enhanced startle. The BNST also receives input from the basolateral nucleus of the amygdala and projects directly to the startle pathway at the level of the nucleus reticularis pontis caudalis. Thus, a pathway going from the visual thalamus to basolateral amygdala to BNST to nucleus reticularis pontis caudalis may mediate light-enhanced startle.

Corticotropin Releasing Hormone-Enhanced Startle

The intraventricular administration of the peptide CRH produces a variety of behavioral and neuroendocrine effects similar to those seen during fear and anxiety. Intraventricular administration of the CRH antagonist α -helical CRH(9–41) blocks the behavioral and neuroendocrine effects of natural stressors

or conditioned fear. The intraventricular administration of CRH increases the acoustic startle reflex. This effect can be blocked by the benzodiazepine chlordiazepoxide, suggesting that the excitatory effect of CRH on startle reflects an anxiogenic effect of the hormone. This effect still occurs after adrenalectomy, indicating that it is not dependent on the release of corticosterone from the adrenal glands. Thus, CRH-enhanced startle represents yet another example of a long-lasting, unconditioned, anxiogenic effect. Chemically induced lesions of the BNST, but not of the amygdala, block CRH-enhanced startle. Moreover, local infusion of CRH into the BNST, but not into the CeA, increases startle amplitude. Hence, CRH-enhanced startle is more similar to light-enhanced startle than fear-potentiated startle in terms of its dependence on the BNST versus the CeA.

Drug Withdrawal

Several studies in both rats and humans have shown that alcohol withdrawal increases acoustic startle amplitude. In rats, nicotine withdrawal or withdrawal from chronic diazepam also increases startle amplitude. In contrast, naloxone-precipitated opiate withdrawal depresses startle markedly. Withdrawal from stimulants such as cocaine or amphetamine has little effect on startle.

Maternal Separation

Exposing rat pups to moderate periods of maternal separation (180 min/day during postnatal days 2–14) increases the adult HPA response to acute air puff startle compared to nonhandled or normally reared rat pups. These animals also show an elevation of the acoustic startle reflex. In contrast, brief (15-min) periods of maternal separation during that same neonatal period renders these animals hypo-responsive to air puff startle (and other psychological stressors) as adults compared to nonhandled rat pups. This alteration in sensitivity and reaction to an acute air puff stimulus may be due to persistent changes in the central GABA, norepinephrine, and CRH systems, as well as in hippocampal glucocorticoid receptor expression.

Other Stressors

In rats, startle is increased during frustrative nonreward, but is decreased following cold swim stress or food, water, or sleep deprivation. In humans, the eye-blink component of startle is increased when elicited in the presence of noxious odors or heat (47–49°C) applied to the thumb. However, anticipation of giving a speech produces a pronounced decrease in startle amplitude, even though this is a very anxiogenic event

for humans. Although the pattern of data is by no means clear, it appears that stressors that direct attention inward (food, water, sleep deprivation, and hypothermia) depress startle, whereas stressors that direct attention outward (threat of shock, a predator, and a harmful environment) tend to increase startle amplitude.

Other Startle Phenomena

Habituation and Dishabituation

When a startle stimulus is repeated relatively rapidly (e.g., once every 10–15 s), the amplitude of the startle reflex will generally decline over repeated test trials, a phenomenon called habituation. In general, the rate of response decrement within a test session is faster with short intervals than with long intervals between stimuli (interstimulus intervals) and with weak startle stimuli than with strong startle stimuli. In contrast, across-session habituation (e.g., measured several hours later or the next day) is generally greater following long intertrial intervals than short intertrial intervals and loud startle stimuli than weak startle stimuli, provided that a common test interval or test intensity is used to assess the level of habituation.

If, following habituation, a novel intense stimulus is presented, the startle amplitude may increase above its habituated level, a phenomenon called dishabituation. It is generally believed that dishabituation is a special case of sensitization and that habituation and sensitization represent separate processes that summate to form the final response amplitude at any given time. In fact, a loud startle stimulus may produce both habituation and sensitization, which jointly determine startle amplitude.

By eliciting the startle reflex electrically via the implantation of tiny electrodes at different levels of the startle pathway, researchers concluded that short-term habituation may result from a change in transmission at the nucleus reticularis pontis caudalis. Because lesions in a variety of brain areas fail to alter the rate of short-term habituation of the startle reflex, it may involve processes intrinsic to the startle pathway, such as receptor desensitization or the buildup of a very local inhibitory process.

However, brain areas extrinsic to the startle pathway itself may mediate long-term habituation. Leaton and Supple have shown that lesions of the cerebellar vermis, which is not part of the acoustic startle pathway, significantly attenuates the decrease in startle amplitude seen across daily test sessions, without affecting the rate of response decrement within test sessions. This blockade of long-term habituation was observed with two different stimulus intensities and

cannot be explained by ceiling or floor effects caused by cerebellar lesions.

Sensitization of startle may also involve brain areas extrinsic to the startle pathway. Borszcz and colleagues found that loud startle stimuli produce sensitization that can best be described as fear of the experimental context in which startle is measured. Reintroducing animals into this context produces a good deal of freezing, a reliable index of fear. Fear of the context elevates startle on subsequent test sessions, leading to a reduction in the amount of long-term response decrement. Treatments such as lesions of the amygdala or drugs such as diazepam, which reduce fear in many situations, facilitate the degree of long-term response decrement, presumably by blocking sensitization and hence allowing long-term habituation to be revealed.

Prepulse Inhibition

The amplitude of the startle response is reduced when the strong startle-eliciting stimulus is preceded shortly (30–500 ms) by a weaker stimulus, or prepulse. This phenomenon, termed prepulse inhibition (PPI), may be a measure of the gating or filtering of sensory information. PPI may be mediated by prepulse inputs to the inferior and superior colliculi, which activate the pedunculopontine tegmental nucleus. This structure, in turn, sends inhibitory cholinergic projections to the caudal pontine reticular nucleus.

A cortico-pallido-striato-pontine circuit connecting limbic cortical regions and subcortical dopaminergic systems to the pedunculopontine tegmental nucleus modulates PPI. These pathways are primarily glutamatergic, dopaminergic, or GABAergic. Both glutamate and dopamine have been implicated in the modulation of PPI, glutamate as a facilitator via subcortical NMDA receptors and dopamine as an inhibitor via D2 receptors in the nucleus accumbens. In the presence of excess mesolimbic dopamine, the pedunculopontine tegmental nucleus is inhibited both directly and indirectly (through the ventral pallidum) by accumbal efferents. The inhibition of the pedunculopontine tegmental nucleus would then block the prepulse from activating this structure and thus reduce its inhibitory effect.

The disruption of prepulse inhibition in rats by dopamine agonists or stress has received particular consideration as an animal model of the putative attentional impairments underlying the positive symptoms of schizophrenia thought to be associated with excessive dopamine transmission. Reduced PPI is also observed in other disorders characterized by sensorimotor and cognitive gating deficiencies, including Huntington's disease, obsessive-compulsive disorder,

attention deficit disorder, and Tourette's syndrome. Schizophrenic patients are often unable to sustain voluntary attention or filter irrelevant thoughts and stimuli. Several neuroimaging studies of schizophrenics have demonstrated anatomical, metabolic, and cellular abnormalities in the cortico-striato-pallido-pontine circuitry modulating PPI, which may underlie these deficits. This model is currently being used to investigate the genetic and early environmental contributions to PPI deficiency, as well as to screen potential antipsychotics.

Glossary

Chromatin

A complex of nuclear DNA and basic proteins called histones. Every 146 bp of nuclear DNA is wrapped around a histone octamer into a nucleosome. A 30-bp DNA linker connects one nucleosome to the next, forming a nucleosome necklace. Intracellular transcription factors that are induced by the specific and high-affinity binding of ligands to exert positive or negative effects on the expression of target genes by different mechanisms.

Steroid hormone receptors (SHRs)

<i>Steroid hormones</i>	Lipophilic hormones derived from cholesterol and synthesized in the adrenal cortex (glucocorticoids, mineralocorticoids, and adrenal androgens), the testes (testicular androgens and estrogen), and the ovary and placenta (estrogens and progestagens).
<i>Transcription factors (TFs)</i>	Nuclear proteins interacting with the regulatory regions of genes, promoters, and enhancers. They can be divided into general transcription factors, forming the transcription initiation complex required for the transcription of all genes, and sequence-specific transcription factors, which bind to specific DNA sequences present in only a subset of genes and carry activation or repression domains that serve to activate or repress transcription.

Steroid hormone receptors (SHRs) are ligand-activated transcription factors and the key mediators of steroid hormone action. Lipophilic steroid hormones pass the cell membrane of target cells by simple diffusion and bind to soluble intracellular SHRs that are complexed to chaperones, such as Hsp90, or to a small fraction of membrane-tethered SHRs. Chaperones are proteins that help other proteins fold and prevent aggregation. The binding of agonistic or antagonistic ligands leads to different allosteric changes of receptors, making them competent to exert positive or negative effects on the expression of target genes by three mechanisms. First, ligand-bound SHR complexes can bind to short, specific DNA sequences in the vicinity of target genes, termed hormone response elements (HREs). The HRE-recruited hormone–receptor complexes are then able to relay activating or repressing signals to the target-gene transcription machinery (Figure 1a). Second, the SHR response can be integrated into intracellular signal transduction pathways that transmit an extracellular growth factor signal via mitogen-activated protein kinases (MAPKs) to a nuclear transcription factor that activates a target gene (Figure 1b). Third, through protein–protein interactions, SHRs can repress the activity of many genes that are switched on during the stress response (transrepression) (Figure 1c).

Historical Development

The gonads and adrenal gland produce five major groups of steroid hormones: estrogens, progestagens, androgens, glucocorticoids, and mineralocorticoids. The effects and clinical symptoms associated with a reduced level of these hormones were known long before the hormone concept was developed. Aristotle, for instance, identified the consequences of castration in humans and birds, and in 1855 Addison described

the symptoms of chronic adrenal insufficiency. Moreover, since the nineteenth century it has been known that female sex steroid hormones play a pivotal role in promoting mammary tumor growth, similar to androgens promoting the growth of prostatic neoplasms. Between the tenth and sixteenth centuries, Chinese alchemists developed empirical methods to purify steroids to near homogeneity. In the first half of the twentieth century, it became possible to isolate individual steroids from extracts derived from source tissues by employing biological complementation assays. When tritium and ^{14}C -labeled hormone compounds of high specific activity became available in the late 1950s, it became possible to follow the fate of the steroid hormones up to their target tissues. Thus, it could be shown that the hormone itself, not a metabolite, produced the response via the activation of gene expression mechanisms. The concept that steroid hormones are involved in transcriptional control was also triggered by the observation of ecdysone-induced giant chromosome puffs by Clever and Karlson in 1960. Some 10 years later the groups of Jensen and Gorski had established a two-step model that involved the binding of the hormone to specific high-affinity SHRs within the target cells, followed by the activation of the hormone–receptor complex in order to induce the expression of hormone responsive genes (Figure 1a). After another 10 years, the hormone receptors for glucocorticoids and estrogens were cloned and thus became the first molecularly defined transcription factors for RNA polymerase II. At around the same time, the cloning of some SHR targets, such as the human metallothionein gene and the mouse mammary tumor virus genome, led to the identification of the first HREs. Within the last 15 years, many details of the SHR signal transduction pathway, including new mechanisms, have been discovered (Figures 1b–c).

Steroid Hormone Receptors Form a Subgroup within the Nuclear Receptor Family

In addition to the hormone receptors for glucocorticoids and estrogens, which were cloned first, receptors for the remaining three major steroid hormone classes have been identified and characterized extensively, as well as a second estrogen receptor and three estrogen-related receptors. All SHRs are characterized by a central DNA-binding domain (DBD) that targets the receptor to the HREs and by a ligand-binding domain (LBD) that is required for switching the receptor's functions. When the *v-erbA* oncogene was cloned, it turned out to also contain a DBD and a LBD that were homologous to the cognate regions of

Figure 1 Three implementations of the SHR signal transduction pathway. a, Ligand-bound SHR complexes binding to short, specific DNA sequences in the vicinity of target genes; b, SHR response being integrated into intracellular signal transduction pathways; c, SHRs repressing the activity of genes that are switched on during the stress response. In a, the lipophilic steroid hormones (depicted by the chemical formula showing the central sterane building block of all steroid hormones) pass the cell membrane of target cells by simple diffusion and bind to soluble intracellular SHRs that are complexed to chaperones such as Hsp90 (shown as ellipses with various colors). Binding of the hormone leads to an allosteric change of the receptor, resulting in the dissociation of chaperones (dashed arrow). The liganded SHR-complexes dimerize, bind to hormone response elements (HREs, dashed arrow) in the vicinity of target genes, and transmit activating (or repressing) signals to the target genes' transcription machinery. In b, an extracellular polypeptide growth factor signal (pink squares) is received by the target cell via membrane receptors with kinase activity that dimerize on ligand binding. The dimerized growth factor receptors relay the signal through a cascade of mitogen-activated protein kinases (MAPKs; arrows) to sequence specific transcription factors (TFs) that are induced (or repressed) by phosphorylation (P) to activate the target gene. Hormone-activated SHRs can bypass a growth factor receptor-mediated signal by activating MAPKs and vice versa. In addition, hormone receptors form complexes with cytoplasmic kinases (green ellipsoid) such as ERK and MSK1 that are activated (phosphorylated) on hormone binding and activate (phosphorylate) the receptor. The complex of activated receptor and kinase(s) is recruited to the target promoter where it phosphorylates histones (brown rectangle) as a prerequisite for chromatin remodeling and transcriptional activation. In c, many immunoregulatory genes as well as genes involved in inflammation are positively regulated by the heterodimeric sequence-specific transcription factor activator protein 1 (AP-1) recognizing a TPA response element (TRE) within the promoter of a target gene. Through protein-protein interactions, ligand-activated SHRs are able to repress in trans the AP-1 activity (transrepression).

the known SHRs. Later on, the *c-erbA* locus was identified as the receptor for the thyroid hormone T_3 , which is also a hormone found in the nucleus like steroid hormones. The identification of another structurally related receptor for the vitamin A metabolite retinoic acid solidified the concept of a nuclear receptor superfamily. Today, more than 520 different nuclear receptors have been described from more than 120 metazoan species, among them receptors for the known nuclear hormones and a vast number of so-called orphan receptors with no, or unknown and possibly novel, ligands. In order to avoid the coining of several trivial names for the same gene, an official nomenclature system has been in use since 1999 (NUREBASE). The SHRs and steroid hormone-like receptors form the nuclear receptor subfamily 3 (NR3), consisting of three groups: A, B, and C (Figure 2a). NR3 includes two receptors for estrogens ($ER\alpha$ and $ER\beta$, or NR3A1 and NR3A2), three estrogen-related orphan receptors ($ERR\alpha$, $ERR\beta$, and $ERR\gamma$, or NR3B1, NR3B2, and NR3B3), and one receptor each for the other major steroid hormone classes: glucocorticoids (GR, or NR3C1), mineralocorticoids (MR, or NR3C2), progestagens (PR, or NR3C3), and androgens (AR, or NR3C4).

Domain Structure of Steroid Hormone Receptors

All SHRs are modular proteins composed of distinct regions, as shown in Figure 2b (top line). When the chicken estrogen receptor cDNA became available, comparison with the human estrogen and glucocorticoid receptor sequences led to the region A–F nomenclature, which is used for all members of the whole nuclear receptor superfamily today. From numerous functional and structural analyses, it became clear that these distinct regions correspond to functional and structural units called domains. Region C (the DBD) and region E (the LBD) display a high degree of sequence conservation, whereas no significant conservation is detected between paralogous SHRs for the regions A/B, D, and F.

Region D is considered a flexible hinge region between the DBD and LBD. Its very N-terminus is an integral part of the DBD and is involved in DBD dimerization. The F region is essential for hormone binding in the PR, GR, and AR but not in the $ER\alpha$. This domain is also important for the discrimination between agonistic and antagonistic hormone ligands. The A region is highly conserved between chicken and human estrogen receptors, but this distinction is much less clear in the other steroid receptors. Therefore, regions A and B are combined into an A/B region in most cases.

Regions C and E are not only responsible for DNA and ligand binding, respectively, but they do encode other functions as well (Figure 2b, bottom). The intracellular distribution of steroid receptors is the result of nuclear-cytoplasmic diffusion and cytoplasmic-nuclear shuttling. At equilibrium, the majority of steroid receptors are in the nucleus due to the presence of nuclear localization signals (NLS), which are believed to be required for nuclear pore recognition. A constitutive NLS is located at the border of regions C and D, whereas a second NLS in the LBD is ligand-dependent. Intracellular localization is different for GR and MR because hormone-induced nuclear translocation has been reported in these cases.

Most SHRs bind as homodimers to their cognate response elements within the promoters of target genes, which is a specific characteristic of this subfamily within the nuclear receptor superfamily. It is also well known that the predominant form of the GR is monomeric in solution and that dimerization occurs only after binding to an HRE, accounting for the cooperativity observed during DNA binding. Responsible for dimerization are a weak dimerization domain encoded within the DBD and a strong dimerization interface provided by the LBD.

Ligand binding confers transcriptional competence on to SHRs that is exerted in most receptors by two independent transactivation functions: a constitutively active one in the A/B region located close to the DBD, referred to as activation function 1 (AF-1; also called τ -1 or enh-1), and a ligand-inducible activation function in the LBD, called AF-2. AFs connect the receptor to the transcription apparatus via direct interactions with basal transcription factors, sequence-specific transcription factors, and/or coregulators.

Individual Family Members

The human estrogen receptor (now called $hER\alpha$, Figure 2a) was cloned from a cDNA expression library produced from the breast cancer cell line MCF-7. A second estrogen receptor, $ER\beta$, has been characterized that is very similar to $ER\alpha$ in terms of structure and function but also shows subtle and important functional differences. Both receptors bind the ligands estradiol, diethylstilbestrol, estriol, and estrone with high affinity. cDNA clones for $hERR\alpha$ and $hERR\beta$ were isolated from a human testis cDNA library using the $hER\alpha$ DBD as a probe. Mouse $ERR\gamma$ was identified by yeast two-hybrid screening, using the transcriptional coactivator GR interacting protein 1 as bait. It is still unclear whether the ERRs are true orphan receptors in search of a ligand or are ligand-independent.

Figure 2 The human steroid hormone receptor family. a, Structure of all family members, cognate ligand, and DNA-binding mode; b, SHR domain structure and structure–function relationships; c, an SHR homodimer bound to its cognate hormone response element (HRE). In a, the numbers refer to amino acid positions. Highlighted are the DNA-binding domain (DBD; shown in blue) and the ligand-binding domain (LBD; shown in red). The A/B and F domains are drawn to scale, and the name of each receptor is indicated (trivial and name according to nomenclature scheme). In c, the HRE is of an inverted repeat (IR) type (palindrome), and half-sites (arrows) are separated by three unspecified (N) nucleotides (IR3-HRE); the hormone ligand is indicated by a sterane formula. AF-1 and -2, transcription activation functions 1 and 2; AR, androgen receptor; ER, estrogen receptor; ERR, estrogen-related receptor; GR, glucocorticoid receptor; h, human; MR, mineralocorticoid receptor; PR, progesterone receptor.

For the GR, two different classes of cDNAs have been described in humans, termed hGR α and hGR β , which are the result of alternative splicing from a single gene transcript. Both isoforms are identical up to amino acid 727 and then diverge, with hGR α being

slightly larger (777 amino acids) than hGR β (742 amino acids). In contrast to hGR α , which is commonly referred to as the bona fide hGR, hGR β was long dismissed as a cloning artifact but has now been shown to be expressed at modest but varying levels

in a range of tissues. Each variant mRNA is translated from at least eight initiation sites into multiple GR α and possibly GR β isoforms, amounting to a multitude of GR monomers and probably a plethora of homo- or heterodimers of unknown function. hGR β does not bind hormones, is transcriptionally inactive, and therefore acts as a ligand-independent negative regulator of glucocorticoid action in transfection experiments. However, the β isoform is not conserved across species, and functional evidence that implicates hGR β in glucocorticoid insensitivity is still missing. hGR α shows a high affinity for the artificial glucocorticoid dexamethasone, moderate affinity for the physiological steroids cortisol and corticosterone, and low affinity for mineralocorticoids and progesterone. In contrast to all other SHRs, GR α dimerizes only weakly.

The progesterone receptor was the first SHR shown to exist in two common isoforms generated by differential promoter use. One promoter initiates transcription at positions +1 and +15 of the gene, which gives rise to the longer isoform B (Figure 2a). The second promoter initiates hPR transcripts between +737 and +842, encoding the 164-amino-acid residues shorter hPR form A. Only PR-B harbors a third activation function (AF-3) at its specific N-terminus, which functions promoter- and cell-specifically. Both isoforms, therefore, display differential target gene specificity. First regarded as an exception in the family, differential promoter use and alternative splicing are now considered the rule for all members. Both PR isoforms show a high affinity for the natural ligand progesterone and the synthetic agonist R5020. Alternative splicing can also generate truncated forms of PR that are found in breast cancer.

The human mineralocorticoid receptor (hMR) and androgen receptor (hAR) were cloned 2–3 years after the GR was described. The hAR exists in two isoforms, hAR-A and hAR-B, which are structurally analogous to the two hPR isoforms. In contrast to hPR-A/B, hAR-A is expressed at substantially lower levels than the B form and its contribution to androgen action is not known. The hAR binds the two naturally occurring ligands dihydrotestosterone and testosterone with high affinity, whereas the hMR shows high and equivalent affinity for aldosterone, physiological corticosteroids, and progesterone.

Heterooligomeric Complex and Ligand and DNA Binding

Heterooligomeric Complex

In 1965, the groups of Jensen and Gorski showed that specific and high-affinity binding sites for estrogen

existed in large heterooligomeric complexes migrating with 9S on low-salt sucrose gradients. This non-DNA-binding complex can be transformed into a more compact and protease-resistant 4S DNA-binding form by high salt and temperature or hormone. The 9S heterooligomeric receptor complexes were later shown to be composed of the two chaperones – heat shock protein (Hsp)90, recently identified as a member of the GHKL family of ATPases, and Hsp70 – plus a number of co-chaperones.

Hsps form an evolutionarily very conserved group of stress-inducible proteins. Contrary to their name, Hsps are strongly induced not only by heat shock, but are also expressed constitutively at physiological temperatures at significant levels. Hsps belong to a larger family of chaperones that are known to stabilize the native structure of other polypeptides by controlled binding to them.

Most investigations have been performed with the heterooligomeric GR complex that contains a dimer of Hsp90 and a substoichiometric amount of Hsp70 and one or two molecules of p23. The last two are required for the assembly of the final heterooligomeric complex. The crystal structure of full-length yeast Hsp90 in complex with an ATP analog and the yeast p23 homolog has been solved recently. For PR and AR, the LBD is sufficient for an interaction with Hsp90 that also requires ATP. In case of the GR, a seven-amino-acid segment overlapping the N-terminus of the LBD, which is located on the surface of the LBD at the opening of the ligand-binding pocket, is sufficient and required for Hsp90 binding. In case of the ER, in addition to the LBD, part of the hinge region D stabilizes the Hsp90–ER complex. From the known crystal structures of a number of LBDs of nuclear receptors and several biochemical studies, it becomes clear that Hsp90 recognizes two hydrophobic surfaces at opposite sides of the LBD located in the vicinity of the ligand-binding pocket. The large distance between the two hydrophobic surfaces probably accounts for the fact that two Hsp90 molecules are bound to SHRs. The LBD of the receptor must be in a complex with Hsp90 in order to have high ligand-binding activity. Hsp90 binding seems to be a characteristic of SHRs because other nuclear receptors, such as the retinoid, thyroid hormone, and vitamin D₃ receptors, do not associate efficiently with these Hsps.

The complexes also contain one of a number of tetratricopeptide (TPR) domain immunophilins that bind to a TPR acceptor site at the C-terminus of Hsp90. Immunophilins are characterized by their peptidylprolyl isomerase (PPIase or rotamase) domains and can function as chaperones like Hsps. SHR complexes contain one of three immunophilins (FKBP51,

FKBP52 or Cyp-40) or PP5, a protein phosphatase that contains both a TPR domain and a PPIase homology domain. The PPIase domain of immunophilins is a binding site for immunosuppressant drugs such as FK506 or cyclosporine A that inhibit PPIase activity on binding.

In hormone-free cells, steroid receptors shuttle between the cytoplasm and nucleus. The distribution may be predominantly cytoplasmic (GR) or nuclear (ER α). Steroid-dependent transformation of the GR triggers its rapid translocation to the nucleus, possibly involving movement along microtubules driven by the motor protein dynein. In wheat germ extracts, it was shown *in vitro* that wheat immunophilins can link the GR–Hsp90 heterocomplex to cytoplasmic dynein via conserved TPR and PPIase domain interactions. Immunoadsorption of GR from cell lysates of L cells coimmunoadsorbs Hsp90, the dynein intermediate chain, FKBP52, PP5, and dynactin (a subunit of the dynein-associated dynactin complex). If the microtubules are stabilized by taxol, α -tubulin is coimmunoadsorbed as well.

All these data are derived from *in vitro* experiments with cell extracts in which the cellular microenvironments are destroyed, so that the observed complexes may be artificial. But a number of *in vivo* observations indicate that the heterooligomeric receptor complex is also of functional importance. Increased levels of FKBP51 have been reported to be the common cause of glucocorticoid resistance in three New World primates, due to delayed translocation of the GR to the nucleus. Likewise the overexpression of FKBP51 in COS cells reduces the hormone binding activity of GR and hence its transcriptional activity. In yeast cells, the overexpression of FKBP51 has no effect, whereas FKBP52 enhances GR-dependent transcription that is dependent on interaction with Hsp90 and PPIase activity. It could be shown that the binding of FKBP52 to Hsp90 potentiates glucocorticoid-dependent reporter gene activity in yeast and mammalian cells that is dependent on PPIase activity and increases the hormone binding affinity of the receptor. Moreover, differential binding of FKBP51 and -52 to dynein corresponds to a differential effect on nuclear translocation. The co-expression of dynactin and the PPIase domain, as well as PPIase domain-swapping experiments, demonstrated the relevance of the dynactin complex for receptor function. Hsp90 and the co-chaperone p23 have been shown to colocalize *in vivo* at genomic HREs in a hormone-dependent manner. p23 seems to be involved in disrupting receptor-mediated transcriptional activation *in vivo* and *in vitro* and, thus, it could be involved in terminating the hormone response.

Therefore receptor-associated chaperones and co-chaperones can no longer be viewed as simple repressors that have to be removed by hormone in order to transform the non-DNA-binding heterooligomeric complex into a DNA-binding entity; they are, instead, viewed as chaperone complexes that accompany all steps in the life of these client proteins: folding, assembly of quaternary structures, intracellular transport, and targeting for proteolytic degradation.

Ligand Binding

Although not proven formally, it is believed that the lipophilic steroid hormones, as well as synthetic compounds with agonistic or antagonistic effects, enter the target cell by simple diffusion and bind to SHRs within the heterooligomeric complex. For hER α and hPR, the three-dimensional structure of their ligand-binding domains complexed with 17 β -estradiol and the antihormone raloxifene or progesterone, respectively, have been determined. Like other known LBDs of nuclear receptors, the LBDs of SHRs are folded into a three-layer antiparallel α -helical sandwich that creates a wedge-shaped molecular scaffold with the ligand-binding cavity at the narrower end of the domain (Figure 3). This cavity is completely partitioned from the external environment and is closed by helix 12 of the LBD, operating as a lid after the hormone has entered the binding pocket. The relocation of this amphipathic helix 12 over the hormone-binding site generates a new surface that allows coactivators to bind to the LBD, thereby mediating the activity of AF-2, which forms the core of helix 12. The LBD dimerization interfaces are formed by α -helices that line up and/or intertwine and differ slightly between ER α and PR.

DNA Binding

The receptors for progestagens, glucocorticoids, mineralocorticoids, and androgens bind to the same HRE that is composed of two half-sites (AGAACA), which are arranged as inverted (palindromic) repeats (IR) with the half-sites being separated by three nucleotides (IR-3). The HRE half-site recognized by both ERs (AGGTCA) deviates in two nucleotides from this DNA sequence (Figure 3c). One HRE half-site is recognized by one receptor monomer, and the homodimer binds in a head-to-head orientation to an IR-3 element. The non-ERs recognize their half-site mainly by a hydrophobic interaction with the methyl group of the thymine in position 4 of the complementary strand (AGAACA) that is not present in the DNA sequence recognized by the ER. The half-site spacing of 3 bp is such that an SHR homodimer binds both half-sites on the same face of the DNA. In addition to IR-3 elements, only the AR is able to selectively

Figure 3 Structure of the human estrogen receptor α . a, Functional domains (A/B to F) of hER α at the primary structure level, with the DNA-binding domain (DBD) and the ligand-binding domain (LBD) highlighted; b, an exploded view of the secondary structure of the hER α DBD bound to DNA, followed by the sequences of the consensus estrogen response element (ERE) and a consensus glucocorticoid response element (GRE); c, crystal structure of the hER α DBD complexed with 17 β -estradiol (E2). In a, The numbers refer to amino acid positions. DBD is highlighted in blue and the LBD in red. The A/B and F domains are drawn to scale. In b, the secondary structure of the DBD is characterized by two steroid hormone receptor-specific zinc fingers. Four cysteines each tetrahedrally coordinate one zinc ion (grey). The Proximal box (P-box) responsible for specific DNA recognition is shown in red; the Distal box (D-box) mediating DBD dimerization is shown in green. In the crystal structure in c, the four amino acid side chains of the P-box (red) are shown interacting with DNA bases (black). These residues are part of an α -helix responsible for specific DNA-sequence recognition that is positioned within the DNA's major groove (perpendicular to the paper plane). A second amphipathic α -helix can be seen to cross the recognition helix with the red P-box residues at a right angle. Between the two helices, the green D-box residues promoting DBD dimerization are located. Underneath the DNA, the sequences of the consensus ERE and a consensus GRE are shown. Both half-sites are organized as an inverted repeat with 3-bp spacing (IR-3). The symmetry axis is indicated by a blue ellipse. The bases that differ between ERE and GRE are highlighted in blue, and the thymine important for the discrimination between both response elements is highlighted in red. In the crystal structure in d, E2, a natural ligand, is shown in yellow. Decisive for a productive interaction with coactivators is the proper positioning of helix 12 (H 12) over the ligand-binding pocket. (We thank R. Hubbard and A. Pike, University of York, UK, for providing this part of the figure.)

recognize direct repeats of the two half-sites separated by three nucleotides (ADR-3 elements). In contrast to other nuclear receptors binding to DR elements, the AR homodimer also binds in a head-to-head orientation to an ADR-3 element.

The DBD of SHRs comprises approximately 80 amino acids encoded by region C plus some 14 N-terminal amino acids of region D. Domain C contains two patterns that are reminiscent of, but clearly distinguishable from, the zinc-finger motifs

first observed in the *Xenopus laevis* transcription factor IIIA. The SHR zinc fingers are also able to tetrahedrally coordinate a zinc atom, but are of the type (Cys2-Cys2). Only very few amino acids, termed the proximal (P-)box, within the first SHR zinc finger are responsible for specific recognition of the cognate HRE. Another set of amino acids, called the distal (D-)box within the second SHR zinc finger, forms the weak dimerization interface of the DNA-binding domain (Figure 3b).

Activation of Transcription

To regulate transcription, agonist-liganded SHRs must talk to the general transcription machinery. This can be achieved either by a direct contact between SHRs and the general transcription factors (GTFs), which are building up the transcription preinitiation complex at the transcription start point, or by means of other cellular factors that do not bind to DNA directly but are recruited to the promoters by the SHRs via protein–protein interactions. Depending on the effect of these coregulators on gene expression, they can be divided into coactivators, which promote transcription mediated by SHRs, and corepressors, which suppress SHR-dependent gene transcription. Coregulators, other sequence-specific transcription factors, and chromatin factors all function as interpreters between SHRs and the general transcription machinery.

Coactivators

Coactivators were originally called transcriptional intermediary factors because they are supposed to bridge between DNA-bound sequence-specific transcription factors and GTFs. The suspicion that SHRs may require coactivators for activation was derived from the squelching phenomenon – the observation that an excess receptor can inhibit its own transactivation as well as transcription by other transactivators. One possible explanation for this behavior is that additional factors, which are present in limited amounts and required for transactivation, are trapped by excess SHRs in unproductive complexes. Conversely, by overexpressing coactivators, it is possible to reactivate a target promoter that has been squelched by excess SHR.

Today, more than 20 of these coactivators are known that were quickly identified within a decade. An important and well-characterized class of coactivators is the steroid receptor coactivator (SRC, or p160) family of coactivators, consisting of its three members SRC-1, SRC-2 (also known as transcription intermediary factor 2 or glucocorticoid receptor-interacting protein 1), and SRC-3. The three related proteins have partial overlapping specificity for hormone receptors and cell type. SRCs enhance hormone-dependent transcriptional activities of SHRs without altering the basal activity of a target promoter. The biological functions of SRCs have been revealed by gene-disruption experiments in mice. Whereas SRC-1-deficient mice display normal growth and fertility but partial resistance to a number of steroid hormones, SRC-2 knockout mice have reduced fertility due to gonadal failure and are leaner because the ratio of white and brown adipose tissue is decreased. The inactivation of SRC-3 has more

dramatic effects and results in growth retardation and smaller body size as well as resistance to growth hormones (GHs) and estrogen. Like SHRs, coactivators are modular proteins with common functional domains such as one that possesses acetyltransferase activity. For the binding to agonist-liganded SHRs, one or several copies of an α -helical LXXLL signature motif, also called a nuclear receptor (NR) box, are required. After the binding of an agonistic ligand to the SHR, helix 12, containing the AF-2 core of the receptor, is relocated, exposing a hydrophobic cleft and an adjacent ionic clamp as the principal determinants for the interaction with an NR box.

In vivo coactivators are organized into complexes that are poised for interaction with SHRs in response to appropriate stimuli. Many of the characterized complexes share subunits, suggesting that a directed or cyclical assembly of coactivator complexes takes place. Current data support a model in which the initial binding of ligand results in the dissociation of corepressors and recruitment of chromatin remodeling machines such as SWI/SNF. The binding of SRCs and other coactivators such as CBP/p300 then results in local acetyltransferase activity and the opening of chromatin in the vicinity of the target promoter. C-terminal SRC-domains can recruit other coactivators, such as the coactivator-associated arginine methyltransferase-1 (CARM1) and cAMP responsive element binding protein (CREB)-binding protein (CBP), and the related protein p300 for complementing and potentiating histone acetyltransferase activity, respectively.

Coactivators are subject to a number of posttranslational modifications for modulating coactivator function. Acetylation and ubiquitination appear to alter the half-life of molecules, whereas phosphorylation is essential for the optimal activity of coactivators within the cell. Phosphorylation of SRCs occurs in response to a plethora of stimuli, including epidermal growth factor, steroid hormones, cytokines, and increased intracellular cAMP. In turn, multiple kinases, such as MAPKs and I κ B kinases, that are involved in a number of cellular signaling pathways are responsible for a distinct phosphorylation pattern on SRC-3, regulating its activity and, more important, its specificity. In contrast to SHRs, SRCs have a broad tissue distribution and coactivate an ever-expanding number of transcription factors. Therefore, coactivators, like SRCs, might serve as integrators of multiple afferent stimuli in order to produce an appropriate cellular response.

Cyclin D1, the regulatory subunit of a holoenzyme that phosphorylates and inactivates the retinoblastoma protein tumor suppressor and promotes progression through the G1-S phase of the cell cycle, has

been identified as a coactivator for ER α recently. The *cyclin D1* gene is frequently overexpressed in human breast cancer and is capable of inducing mammary tumorigenesis when overexpressed in transgenic mice. Cyclin D1 binds to the N-terminal half of the ligand binding domain of ER α and enhances ligand-induced recruitment of ER α to an estrogen responsive element (ERE). More important, cyclin D1 antagonizes the repression of ER α activity mediated by the tumor suppressor gene product BRCA1, which is functioning as a corepressor of ER α in this context. Thus cyclin D1 and BRCA1 constitute an antagonizing pair of coregulators for ER α .

Corepressors

For some members of the nuclear receptor family, such as the thyroid hormone receptor (TR) and the retinoid acid receptors (RARs), that form heterodimers with the retinoid X receptor (RXR), it is well known that they repress basal transcription in the unliganded state. It has been shown that this silencing effect is mediated by corepressors that were called nuclear receptor corepressor (N-CoR) and silencing mediator for retinoid and thyroid hormone receptors (SMRT). N-CoR and SMRT associate with DNA-bound TR–RXR or RAR–RXR heterodimers in the absence of hormone but not in its presence. SMRT and N-CoR are multiprotein complexes that exhibit histone deacetylase activity. Both corepressors are also involved in steroid hormone action because it was demonstrated that the overexpression of N-CoR and SMRT represses the partial agonistic activity of both ER α bound to the antihormone tamoxifen and of PR bound to the antagonist RU486. Recognition by transcriptionally incompetent SHRs of corepressors is mediated by short amphipathic helical signature motifs, called CoRNR boxes, which are similar to the NR boxes of coactivators. Corepressor activity is mediated by histone deacetylation. Because corepressors lack intrinsic deacetylation domains, they recruit histone deacetylases for this task. Apparently, corepressors and coactivators are functionally similar proteins, so it is not surprising that a corepressor can also turn into a coactivator, as shown for N-CoR and RAR.

Recently, the tumor suppressor gene product BRCA1 has been shown to be a corepressor of ER α . BRCA1 is implicated in DNA repair mechanisms, and germ-line mutations in the BRCA1 gene predispose women to ovarian and breast cancer. BRCA1 inhibited estradiol-induced endogenous gene expression at levels of BRCA1 that are within the physiological range. Moreover, BRCA1 was shown to bind to ER α directly *in vitro* and the binding of BRCA1 to an

estrogen responsive gene was reduced by estradiol *in vivo*. BRCA1 appears not to act on specific estrogen responsive genes or gene subsets but blocks the ability of estradiol to alter the expression of the vast majority of all estradiol responsive genes in MCF7 cells. BRCA1 downregulates the coactivator p300, and excess p300 rescues BRCA1 repression of ER α like cyclin D1 can. The physical association of cyclin D1 with ER α may exclude the direct association of BRCA1 with the receptor or alter the conformation of BRCA1 and/or the binding of other BRCA1-associated proteins and thereby contributes to activation at an ERE.

Altogether, SHRs can exist in a multitude of conformations, depending on the nature of bound ligand. The various interaction surfaces are mainly determined by helix 12 and most likely by the C-terminus beyond helix 12, the F region. The transactivation by SHRs appears to be not only a simple net activation but the sum of relief from repression by corepressors and activation by coactivators. The switch from the repressed to the activated state is initiated by the hormone ligand through an allosteric change in SHR structure followed by an intricate interplay of coregulators.

Interactions with Sequence-Specific Transcription Factors

SHRs control the activity of natural promoters through positive and negative interactions with sequence-specific transcription factors. Particularly interesting is an interaction that represses the activity of both partners, as exemplified in the case of hGR and the heterodimeric transcription factor AP-1. Similar interactions have been described between GR and the p65 subunit of the transcription factor nuclear factor (NF)- κ B and the transcription factor GATA-1. From experiments with numerous SHR mutants, it can be concluded that repression is most likely mediated by a protein–protein interaction with an SHR monomer that requires the N-terminal portion of the receptor. Because most immunoregulatory genes as well as genes involved in inflammation are positively regulated by the transcription factors AP-1 and NF- κ B, it is conceivable that the immunosuppressive and anti-inflammatory activities of glucocorticoids are mediated through the inhibition of AP-1- and NF- κ B-mediated transactivation by GR (Figure 1c).

A novel biological action of GR was revealed by constructing mice with the hepatocyte-specific loss of GR that have a severe reduction in body weight due to decreased bone length and size of internal organs, very reminiscent of mice lacking the signal transducer and activator of transcription (STAT)5. In both mice strains, growth hormone (GH) signaling via

the JAK–STAT pathway is impaired. GR directly interacts with both phosphorylated and unphosphorylated forms of STAT5, and both proteins are detectable at promoters of GH-regulated genes *in vivo*, which is essential for GH signaling. As shown by dimerization defective GR mutant (GR^{dim}) mice, GH signaling is independent of GR DNA binding and most likely mediated by protein–protein interaction with STAT5 transcription factors.

Interaction with Chromatin Factors

The interaction of SHRs with DNA, the general transcription machinery, coregulators, and sequence-specific transcription factors takes place in the nucleus with its DNA compacted into chromatin. Genetic analyses have demonstrated a widespread involvement of chromatin structure in gene regulation in general. For the GR, it was shown that components of the so-called SWI–SNF complex, a set of pleiotropic transactivators that counteract the repressive functions of chromatin, are required for transactivation in yeast. In human cells lacking brahma (hBrm), the homolog of the SWI–SNF complex subunit SWI2, transactivation by GR is weak and can be enhanced selectively by the ectopic expression of hBrm. Like SWI2 in yeast, hBrm is part of a large multiprotein complex that mediates the ATP-dependent disruption of a nucleosome. A direct interaction between nuclear receptors and components of hBrg1, a brahma-related ATPase complex, has been demonstrated, and chromatin immunoprecipitation experiments indicate that the hormone receptors recruit these ATP-dependent chromatin remodeling complexes to their target genes. In the case of the MMTV promoter, activation by glucocorticoids and progestins depends on the correct organization of the promoter sequences in nucleosomes so that some HREs of a larger cluster get exposed. The binding of the receptor to the exposed HREs leads to the recruitment of ATP-dependent chromatin remodeling activities that displace H2A–H2B dimers from the promoter and allow the binding of the ubiquitous transcription factor NF1 and the recruitment of more receptor molecules, followed by coactivators and the transcription preinitiation complex. Optimal activation requires the inclusion of linker histones that help to position nucleosomes and generate a more suitable platform for receptor binding.

Apart from the SWI/SNF complex and related ATP-dependent chromatin remodeling machines, increasing evidence has implicated the modification of histones in the regulation of gene transcription. Histones are composed of a histone fold domain, involved in wrapping the DNA in nucleosomes, and an N-terminal tail rich in lysine that protrudes out of

the nucleosome. The acetylation of tail lysines reduces the affinity of histone tails for DNA greatly and is believed to render DNA more accessible to transcription factors while still maintaining a nucleosomal architecture. Moreover, some of the identified coactivators for SHRs, such as CBP/p300 and SRC1, as well as the largest subunit of the pivotal GTF TFIID, TAF_{II}230/250, turned out to be histone acetyl transferases (HATs). All of these observations led to the current two-step model for transcriptional activation by SHRs that is built on the hormone-mediated recruitment of coactivators and other transcription factors with HAT activity, resulting in the local destabilization of repressive histone–DNA interactions, followed by direct or indirect interactions with the basal transcription machinery. Histone arginine methyl transferases, such as CARM1, are also implicated in gene activation by steroid hormones. and recent evidence suggests a participation of kinases that phosphorylate core and linker histones. Altogether, these new findings emphasize the importance of chromatin remodeling in gene regulation by steroid hormones.

Recently, a detailed kinetic analysis by chromatin immunoprecipitation (ChIP) analyses of the assembly of transcription initiation complexes on the estrogen responsive promoter of the pS2 gene has revealed a sequence of cycles of formation of multiprotein complexes involving protein-modifying enzymes and ATP-dependent chromatin remodeling complexes, followed by ubiquitin/proteasome-mediated degradation of the receptor with a cycling amplitude on a time scale of minutes. The dynamic nature of transcriptional activation has also been assessed by single live-cell imaging of transcription factors tagged with fluorescent proteins. Contrary to the ChIP results, fluorescence recovery after photobleaching analyses have shown that SHRs and interacting coregulators rapidly exchange on large artificial HRE arrays on a time scale of seconds. In attempting to reconcile these contradictory results, we have to consider that ChIP is a composite freeze-frame of promoter occupancy in millions of cells, whereas live-imaging focuses on the chronology of events in a single cell.

Involvement of the Glucocorticoid Receptor in the Stress Response

Studies of human patients and adrenalectomized animals have shown that glucocorticoids have a plethora of functions, the most important being the stimulation of gluconeogenesis; decrease of glucose uptake by peripheral tissues; increase of glycogen deposition; increase of lipolysis; stimulation of protein and nucleic acid synthesis, predominantly in the liver; suppression of immune and inflammatory responses;

inhibition of fibroblast proliferation and extracellular matrix deposition; maintenance of normal cardiovascular function and blood pressure; and regulation of calcium absorption. Many of these functions should prevent an overreaction of defense mechanisms to stress and be conducive to coping with the stress response. In line with this hypothesis, the synthesis and release of glucocorticoids are elevated during stress, and people with chronic adrenal insufficiency show “general languor and debility, remarkable feebleness of the heart’s action, irritability of the stomach and a peculiar change in the color of the skin,” as Addison described it in 1855. Although none of these symptoms is life-threatening, patients with Addison disease cannot withstand stress and are prone to suffering an acute adrenal crisis that can lead to shock or coma.

Until recently, it was believed that all these glucocorticoid effects were of a genomic nature, mediated by its receptor binding to glucocorticoid response elements (GREs) in the target genes. Given the multiple important functions of glucocorticoids, it was therefore not surprising to learn that GR-deficient mice, which were generated using gene knockout techniques, are not viable and die shortly after birth.

However, the cause of death – respiratory failure due to lack of lung maturation – does not seem to depend on genomic effects mediated by GREs. Contrary to GR-deficient mice, homozygous mice that express a mutated GR that is not able to dimerize appear almost normal and healthy under standard laboratory conditions. This dimerization-defective GR (GR^{dim}) can no longer bind efficiently to palindromic GREs, and these mutant mice do not respond to the administration of glucocorticoids by the induction of well-characterized hormone responsive genes. Clearly, GRE-mediated gene activation is not required for development and survival. On the other hand, GR^{dim} mice show a selective impairment of spatial memory in the water maze. It is known that the stress that is associated with a learning task – here orientation in a maze – leads to the activation of GRs in the brain, which is required for facilitated storage of the acquired information. Therefore, the facilitating effects of corticosterone on spatial memory seem to depend on DNA binding of the GR.

There is also increasing evidence that altered GR signaling is an important cause of the pathogenesis of major depression. The most consistent biological finding in patients with depression is hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis. Mutant mice with a 50% GR gene dose reduction have a disinhibited HPA axis like human patients and show increased helplessness after stress exposure, a behavioral correlate of depression in mice. In contrast, mice that overexpress GR demonstrate a reduced

helplessness response after stress challenge. Also, human carriers of two polymorphisms in the GR gene had an increased risk of developing a major depressive mode.

Cross-Talk with Other Signal Transduction Pathways

Steroid hormones can either act via their cognate receptors that alter gene expression after binding to HREs in target genes (termed genomic or nuclear action) or act via membrane-bound or -localized SHRs or non-SHRs (termed nongenomic or cytoplasmic action). Whereas genomic action is slow and takes 30–60 min, nongenomic action is rapid and takes a couple of seconds or minutes. We now briefly summarize the important findings on nongenomic actions that involve the classical steroid receptors.

The existence of such nongenomic actions became apparent in experiments with GR knockout mice that die postnatally and with mice that express a dimerization-defective mutant GR and are viable. The dimerization-defective GR shows impaired GRE-dependent transactivation while functions that require cross-talk with other transcription factors remain intact. Moreover, many studies employing different techniques and assays have shown that a small pool of estrogen (some 2%) and ARs are associated with the plasma membrane. More specifically, both receptors have been identified in the caveolae, together with a number of signaling molecules. One of the actions of steroid receptors thought to take place in the caveolae is the estrogen-mediated rapid increase in endothelial nitric oxide synthase (eNOS) activity. The 110-kDa caveolin-binding protein striatin has been identified as a molecular interaction hub that organizes an ER α -eNOS membrane signaling complex engaging also the G-protein G_{zi}. The disruption of the ER α -striatin interaction abolishes the rapid activation of MAPK, Akt kinase (also called protein kinase B), and eNOS by estrogen, whereas genomic signaling is not affected. But other proteins such as caveolin-1, modulator of nongenomic action of estrogen receptor (MNAR), Shc, or insulin-like growth factor-1 receptor are also implicated in tethering ER α to the inner face of the plasma membrane bilayer. Moreover, the steroid-independent palmitoylation of a cysteine residue within the E domain has been observed. Palmitoylation facilitates caveolin-1 binding as well as membrane localization. Interestingly, A/B and C domain-deleted ER α still localizes to the membrane and signals to extracellular receptor kinase (ERK) like the wild-type receptor. Current evidence suggests that ER α membrane localization is required for kinase activation.

A well-known rapid response of steroid receptors is the activation of the c-Src–p21ras–ERK2 pathway by ligand-bound AR, ER α (but not ER β), GR, MR, and PR-B. For all five SHRs MAPK activation is abrogated in the presence of antihormones, but this is less clear for MR. Although various mechanisms have been proposed, the interaction of SHRs with the kinase c-Src is an important aspect of cross-talk. Whereas AR interacts with the SH3 domain of c-Src, ER α interacts with the SH2 domain. AR activation of the ERK pathway is more effective if, in addition to AR binding to the SH2 domain, ER α simultaneously binds to the SH3 domain. In cells expressing both receptors, stimulation with androgen or estrogen induces a productive ER α –AR–c-Src complex that can be prevented by treating with either antiandrogens or antiestrogens. PR-B does not bind to c-Src directly, but requires the presence of ER α . In the absence of progestins, PR-B (but not PR-A) binds to ER α . Progestins release ER α from this complex and thus trigger the interaction of ER α with c-Src. In case of ER α , cross-talk is exemplified by epidermal growth factor (EGF) treatment of ovariectomized mice. This results in nuclear translocation and an altered phosphorylation state of ER α . Transient transfection studies showed that EGF, thus, can activate ER α .

The activation of the GR elicits apoptosis in T cells, but can paradoxically also promote thymocyte survival. This dual effect is reminiscent of the actions of the T-cell antigen receptor, which is essential for thymocyte survival but can also cause apoptosis. Interestingly, the activation of the T-cell antigen receptor blocks glucocorticoid-induced apoptosis, thus implying functional cross-talk between these two distinct signaling systems. The regulation of programmed cell death by glucocorticoids also involves the regulated expression and alternative splicing of the *bcl-X* gene and crosstalk with the STAT5 family of transcription factors. In lymphocytes, the apoptotic effect is mediated by a selective interaction of GR with activated STAT5a, whereas in mammary cells, equipped with STAT5b, glucocorticoids act as antiapoptotic factors.

The downstream targets of the rapid action of steroids remain to be fully uncovered, but in many cases the SHRs themselves – and their coactivators – are targeted. Therefore, one function of these rapid actions seems to be the potentiation of genomic action. All SHRs have been known to be phosphoproteins for many years. Most of the identified phosphorylation sites are serine and threonine residues, but some of the family members are also phosphorylated on tyrosine. In case of the chicken PR, for instance, four phosphorylated serines have been identified common to both isoforms, PR-A and PR-B. The

two N-terminal sites are only moderately phosphorylated in the absence of hormone, whereas, after hormone treatment, an increase in the phosphorylation of these sites and the appearance of two new phosphorylation sites are observed. The mutation of these serine residues results in a cell- and promoter-specific variation of receptor activity when tested in transfection experiments. In case of ER α ERK, phosphatidylinositol 3-kinase, p90^{RSK}, a kinase downstream of Akt2, and Akt2 itself phosphorylate discrete residues of the receptor, upregulating its transcriptional activity or stability.

Introduction

Cholesterol Side-Chain Cleavage Enzyme: CYP11A1

17-Hydroxylase: CYP17A1

21-Hydroxylase: CYP21A2

11 β -Hydroxylases: CYP11B1 and CYP11B2

Aromatase: CYP19A1

Steroid Catabolism by CYPs

Glossary

<i>Cytochromes P450</i>	Enzymes involved in the hydroxylation of endogenous or exogenous substrates.
<i>Hydroxylation of steroids</i>	Replacement of hydrogen (H) atoms in steroids by hydroxyl (OH) groups.
<i>Localization of steroidogenic enzymes</i>	Specific organs, cell types, or intracellular organelles in which the enzymes, responsible for the biosynthesis of steroids, can be found.
<i>Regulation of steroidogenesis</i>	Processes that play a role in increasing or decreasing the amounts of steroids formed.
<i>Steroid biosynthesis</i>	The process by which hormonally active steroids are formed from cholesterol.

Introduction

The cytochrome P450 (CYP) genes form a family, encoding a class of heme-thiolate enzymes active in the hydroxylation of endogenous and exogenous substances. They are involved in detoxification and catabolism of pharmacological substances and in

biosynthesis of steroids. Homology between the various members is relatively high: CYPs in the same subfamily usually are about 70% similar. These enzymes are instrumental in conveying molecular oxygen to designated positions in the steroid skeleton, in this way introducing hydroxyl groups and determining which final hormonal steroids will be produced in the process of steroid biosynthesis. The specific roles of these enzymes in the pathway of steroidogenesis are indicated in **Figure 1**. The electrons necessary to drive this process are supplied by NADPH or NADH and are passed to mitochondrial CYPs by way of the flavoprotein adrenodoxin reductase to the iron-sulfur protein adrenodoxin. For the CYPs in the microsomal cell fraction, the role of adrenodoxin is taken over by P450 oxidoreductase; cytochrome b5 may play an additional role to support 17,20-lyase activity.

Cholesterol Side-Chain Cleavage Enzyme: CYP11A1

The enzyme CYP11A1 performs the conversion of cholesterol to pregnenolone, by first hydroxylating cholesterol at the 20 α and 22 carbon atoms and then lysing the bond between these carbon atoms. The enzyme, of which only one form is known, is localized in the adrenal glands, the gonads, the placenta, and the brain. Intracellularly, the location is in the inner mitochondrial membrane. Apparently, this localization is extremely important for the activity of the enzyme: transfection studies with constructs that direct the protein into the endoplasmic reticulum failed to show activity.

Regulation of the expression of CYP11A1 differs in different tissues. In organs where an acute stimulation of CYP11A1 transcription can take place under the influence of adrenocorticotrophic hormone (ACTH) or gonadotropins, the adrenals, and the gonads, the responsible cyclic AMP-responsive elements differ from

Figure 1 Localization of steroidogenic enzymes along the pathways leading to the biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids. Shaded boxes indicate the various cytochromes P450 (CYPs). DHEA, dehydroepiandrosterone.

those in the placenta. Furthermore, a number of transcription factors, such as SF-1 and Sp-1, play a role in the stimulation of the transcription of CYP11A1. This transcriptional regulation of the amount of enzymes in the glands takes a relatively long time (2–4 h), whereas the stimulation of steroidogenesis may be much faster. These fast effects of increased cAMP levels are mediated through effects on the transport of cholesterol into the mitochondria by the steroidogenic acute regulatory protein (StAR), which enables cholesterol transport to the mitochondrial inner membrane. StAR is not expressed in brain or placenta. It has become apparent that the inability to lyse the C20–C22 bond of cholesterol, as present in congenital lipoid adrenal hyperplasia, may be due to inactivating mutations in CYP11A1, but can also be caused by inactivating mutations of StAR, indicating the crucial importance of this protein in steroidogenesis.

17-Hydroxylase: CYP17A1

After the conversion of cholesterol to pregnenolone in the mitochondria, further conversion of pregnenolone takes place in the endoplasmic reticulum by the conversion to 17-OH pregnenolone by CYP17A1 or to progesterone by 3β-HSD. Progesterone, in turn, can be converted to 17-OH progesterone by the same CYP17A1, which also contains 17,20-lyase activity to convert 17-OH pregnenolone to dehydroepiandrosterone (DHEA) and 17-OH progesterone to

androstenedione. For this reason, CYP17A1 is at the bifurcation of the steroidogenic pathways to glucocorticosteroids and the sex steroids. CYP17 is expressed in the adrenal glands and in the gonads. The production of DHEA, which might be important as a neurosteroid through its interactions with γ-aminobutyric acid (GABA) and N-methyl-D-aspartate (NMDA) receptors, in the brain is an enigma so far because CYP17A1 has not been detected in the brain, which has led to alternative hypotheses for the mechanisms responsible for the production of this steroid involving reactive oxygen species. The expression of the CYP17A1 gene is mainly regulated by cAMP. Addition of cAMP derivatives can stimulate the transcription of the gene; this activity can be inhibited by the addition of phorbol esters, which act via protein kinase C and growth factors such as epidermal growth factor (EGF) and fibroblast growth factor (FGF).

The separate regulation of 17-hydroxylase and 17,20-lyase activity of the enzyme has been resolved on the basis of the finding of mutated genes, causing the production of 17-hydroxylated steroids, without removal of the C20,C21 side chain. These mutations are localized in the region of the protein, which interacts with the additional electron donor cytochrome b5; lyase activity appears to be more vulnerable to the disruption of interaction with this redox partner than the 17-hydroxylase reaction. Similarly, the changing ratios between the production of glucocorticoids and adrenal androgens, mainly DHEA

sulfate, during human development is likely to be due to a changed expression of cytochrome b5.

The pivotal role of CYP17A1 in steroidogenesis is emphasized by the effects of inactivating mutations in this enzyme: a complete block of 17-hydroxylation leads to the inability to synthesize cortisol, whereas aldosterone will be produced in abundance, giving rise to hypertension. Furthermore, sex steroids cannot be produced, causing undervirilization in boys and absence of puberty in both sexes.

21-Hydroxylase: CYP21A2

CYP21A2 catalyzes the conversion of progesterone to 21-hydroxyprogesterone (deoxycorticosterone, DOC) and of 17-OH progesterone to 17,21-dihydroxyprogesterone (deoxycortisol, compound S). These reactions are a prerequisite to synthesize mineralocorticoids and glucocorticoids; the enzyme is expressed in the cortex of the adrenal gland and is not present in the gonads. Using reverse transcription polymerase chain reaction (RT-PCR), expression of CYP21A2 has also been detected in the brain stem, but not in other regions of the brain.

The expression of CYP21A2 is stimulated by cAMP- and protein kinase C-dependent pathways. In this way, the production of deoxycorticosterone in the zona glomerulosa of the adrenal cortex may be stimulated by angiotensin II, whereas the production of deoxycortisol in the zonae fasciculata and reticularis is ACTH dependent.

Due to the fact that an inactive pseudogene, CYP21A1P, exists in the neighborhood of the CYP21A2 gene on chromosome 6, frequent exchanges between these genes have taken place, leading to impairment of the functioning of the resulting protein, the inability to produce aldosterone, corticosterone, and cortisol, and overproduction of adrenal androgens (in humans). These enzyme deficiencies can lead to salt loss in newborn babies and severe masculinization in girls. In female patients with milder forms of the defect, late onset virilization or hirsutism may be found.

11 β -Hydroxylases: CYP11B1 and CYP11B2

The further conversion of 21-hydroxylated steroids to the main mineralocorticoids and glucocorticoids (aldosterone and cortisol [humans] or corticosterone [rat and mouse]) is affected by CYP11B2 and CYP11B1, respectively. The genes encoding these members of the CYP family are found in close vicinity on chromosome 8q and probably arise from ancient gene duplication. The localization of these enzymes in the adrenal cortex is different: CYP11B1

is localized in mitochondria of the zona fasciculata, whereas CYP11B2 is found in mitochondria of the zona glomerulosa. Furthermore, using RT-PCR, mRNAs encoding these enzymes have been detected in various regions of the brain and in the heart.

The regulation of the expression of the two genes is also different. The expression of CYP11B1 is regulated by the ACTH-driven production of cAMP, followed by activation of a cAMP-responsive element, whereas CYP11B2 is stimulated mainly by angiotensin II, which stimulates the production of inositol triphosphate and diacylglycerol by phospholipase C. This leads to increased levels of intracellular calcium and increased activity of phosphokinase C. In this way, the expression of the two 11-hydroxylases can be regulated separately in the zona glomerulosa and zona fasciculata, respectively, of the adrenal cortex.

The clinical results of deficiencies of either of these enzymes can be predicted on the basis of the steroids, the biosynthesis of which will be blocked. Defective CYP11B1 gives rise to low levels of cortisol that can only be increased by supply of exogenous glucocorticoids. An insufficient production of aldosterone, caused by a mutation in CYP11B2, can be partially compensated by overproduction of deoxycorticosterone, which has mineralocorticoid activity.

Aromatase: CYP19A1

The final steroid-hydroxylating enzyme, which plays a role in the biosynthesis of steroids, is CYP19A1. It is responsible for the hydroxylation of carbon atom C19 of testosterone and androstenedione, the subsequent cleavage of the bond between C19 and C10, and subsequent redistribution of the electrons over the A ring to form the aromatic steroids estradiol and estrone, respectively. Only one copy of the gene has been found. It has a complex structure at the 5' end, allowing start of transcription at a number of sites, under the control of various promoter sequences. This means that in various tissues, different mechanisms can be used for the stimulation of the transcription of the gene: in the gonads and adrenals, a cAMP-mediated mechanism is responsible for the stimulation of CYP19A1 by gonadotropins and ACTH, respectively, whereas in fat cells, cortisol can stimulate the production of estrogens. CYP19A1 is also expressed in a large number of other tissues, such as muscle, bone, and brain. In the latter, estrogens formed by this enzyme may play a role in sexual differentiation.

Defects of CYP19A1 are very rare. However, the clinical picture in patients with mutations in this gene shows profound changes of parameters of gonadal function, bone metabolism, and aspects of the

metabolic syndrome, indicating the role of estrogens in the regulation of numerous aspects of homeostasis.

Steroid Catabolism by CYPs

Apart from their role in the biosynthesis of steroid hormones, enzymes of the CYP family also play important roles in the breakdown of steroids. The most important enzymes in this respect are those of the CYP1 and CYP4 subfamilies. Members of the CYP1 subfamily are important in the hydroxylation of mainly estrogens, where both C2 and C4 may be attacked. CYP4 family members hydroxylate corticosteroids and androgens at the 6 position and can also attach a hydroxyl group at C16. It is important to be aware of the fact that expression of all of these enzymes can be induced by xenobiotics, leading to aberrant metabolism of the steroid hormones and, for example, changes in the ratios between the serum levels of steroids produced in the adrenal gland, which might lead to erroneous conclusions of disturbed steroidogenesis.

Strain Differences

Sources of Genetic Variability

Systems Genetics and Genetic Reference Populations

Glossary

<i>Inbred</i>	Obtained by continuous breeding of closely related individuals so as to preserve desirable traits in a stock.
<i>Inbred strain</i>	A strain of organisms that has been maintained by sibling (sister × brother) mating for 20 or more consecutive generations. Except for the sex differences, mice of an inbred strain are as genetically alike as possible, being homozygous at virtually all of their loci.
<i>Isogenic</i>	Genetically identical (except for sex); coming from the same individual or from the same inbred strain.
<i>Intercross</i>	A cross between two animals that have the same heterozygous genotype at designated loci; for example, between sibling F1 hybrids that were derived from an outcross between two inbred strains.
<i>Quantitative trait</i>	A phenotype that is influenced by multiple genes. Its variation is therefore continuous (skin color, weight, etc.).
<i>Quantitative trait locus (QTL)</i>	A polymorphic site on a chromosome containing alleles that differentially influence the expression of a quantitative trait.
<i>Recombinant inbred (RI) strains</i>	Strains constructed by crossing two inbred strains to produce an F1 generation, followed by 20 or more consecutive generations of brother × sister mating. However, the F1 generation may be produced in other ways, such as crossing mice of either existing RI strains, advanced intercross lines, or multiple inbred strains (e.g., an eight-way cross).
<i>Systems genetics</i>	A method for integrating across scales of organization using genetic reference populations. It summarizes results on molecular networks (gene expression data) associated with single-nucleotide polymorphisms SNPs and structural and functional variations.

Strain Differences

Inbred strains of mice and rats are invaluable animal resources for studying the genetic bases of phenotypic variation. They have been obtained through brother-sister mating for more than 20 generations, so all individuals have the same genome (isogenic) and each individual is homozygous at each locus. In a given environment, strain differences result from differences at the genome level.

Large variations in hypothalamic-pituitary-adrenal (HPA) axis activity have been described among inbred strains of rats and mice. Many of these studies are related to the pathophysiology of immune diseases, in which the HPA axis could play a critical role together with immune mechanisms. The Fischer 344 (F344) and Lewis rat strains particularly were studied in this respect, the Lewis female rats bearing an HPA axis that is less reactive to most stimuli and being more sensitive to induced autoimmune diseases such as streptococcal cell wall-induced arthritis or experimental allergic encephalitis. The sensitivity of the Lewis strain can be restored by the removal of the adrenal glands or by treatment with a glucocorticoid antagonist, and F344 rats become resistant when treated with glucocorticoid hormones. They are also studied in relation with the metabolic effects of corticosteroid hormones in the context of nutrition, obesity, and cardiovascular diseases.

Sources of Genetic Variability

It is not easy to detect the primary change(s) responsible for the functional variations of the HPA axis because phenotypic differences may be multiple and the components of the HPA axis interact strongly with numerous facilitation and feedback mechanisms at every level. For instance, when compared to F344 rats, the inbred brown Norway (BN) rats display a number of differences in their HPA axis function, with a different diurnal pattern of plasma corticosterone levels, a faster recovery after restraint stress, an adrenal gland of larger size but less reactive to adrenocorticotrophic hormone (ACTH), and mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) hypersensitive to their ligands.

Two main strategies are available for exploring the molecular bases of genetic variation. The detailed exploration of phenotypic differences may suggest candidate mechanisms and/or genes to analyze. For

instance, the comparison of BN and F344 rat strains suggested that the MR is a major source of genetic variability. Therefore, the gene encoding MR (named Nr3c2) was cloned in the two strains and sequenced, revealing in the BN strain a mutation in the coding region with an amino acid change in the protein (Y73C) that increases the transactivating properties of MR agonists.

Another approach, known as quantitative trait loci (QTL) analysis, is based on the association between polymorphic anonymous markers and the phenotypic value of the trait under study in a segregating population (such as F2 or backcross). In this approach, there is no need for any assumption about the gene(s) involved. In the case of the BN/F344 comparison, a QTL analysis confirmed the linkage between the mutation in the Nr3c2 gene and several MR-related phenotypes and disclosed several other loci contributing to phenotypic variability of MR- and GR-related phenotypes. Another study in a BN $\times$ Wistar Kyoto hyperactive (WKHA) intercross revealed the contribution of a locus on chromosome 2 influencing poststress levels of renin and aldosterone. In this locus the angiotensin receptor 1b was mapped, which is responsible for angiotensin II (Ang II) effects on aldosterone secretion, and, indeed, differences were found in the response of adrenocortical cell to Ang II stimulation *in vitro*. This example illustrates the power of the QTL approach to reveal candidate genes possibly involved in phenotypic variation, as well as the multiplicity of mechanisms underlying genetic variation in corticosteroid hormone secretion and action.

Systems Genetics and Genetic Reference Populations

An extension of this QTL approach is the use of recombinant inbred (RI) strains, which are constructed by crossing two inbred strains to produce an F1 generation, followed by 20 or more consecutive generations of brother–sister mating. From a single F1 population, as many strains as possible can be derived. Each strain contains a unique, approximately equal proportion of genetic contributions from the two progenitor inbred strains. Instead of having a single individual for each genetic combination, as in an F2 population, each strain represents an unlimited number of animals with the same genotype, so the phenotype can be measured with more accuracy (in several animals instead of a single F2 animal) and different phenotypes measured across studies are cumulative and can be compared. Furthermore, precise genotyping of the strains with sequence-derived single

nucleotide polymorphisms allows precise QTL mapping. For instance the most used set of recombinant inbred strains with approximately 80 strains has been obtained from the C57BL/6 and DBA/2 mouse strains, and much larger sets (up to 1000 strains) are under construction. All data about these strains are integrated in a unique database named WebQTL that allows a large range of data mining from genetic correlation across multiple traits and QTL analysis. As an example, plasma corticosterone levels after an injection of saline (which can be considered as a mild stressor) was studied in 19 strains. In the WebQTL database of published phenotypes, genetic correlations are found between these levels and a number of phenotypes related to neuroanatomical and neurofunctional measures, response to drugs of abuse, and immune and inflammatory processes. This can be also correlated with gene expression data in different tissues. Therefore, these genetic reference populations allow a systems genetics approach that integrates all these data from diverse sources to explore genetic variation in HPA axis and in its target organs as a complex functional system.

Glossary

<i>Akathisia</i>	A state of inner restlessness characterized by pacing, inability to sit still, or other constant urge for movement.
<i>Antipsychotic</i>	A medication used to treat psychosis, i.e. delusions or hallucinations.
<i>Anxiolytic</i>	A medication or treatment used to decrease anxiety.
<i>Anxiogenic</i>	A factor which causes or increases levels of anxiety.
<i>Cholinergic</i>	Related to the neurotransmitter acetylcholine.
<i>Dopaminergic</i>	Related to the neurotransmitter dopamine.
<i>GAD</i>	Generalized anxiety disorder.
<i>Histaminergic</i>	Related to the neurotransmitter histamine.
<i>Hypercortisolemia</i>	An elevated level of the glucocorticoid cortisol in the blood.
<i>OCD</i>	Obsessive-compulsive disorder.
<i>Presynaptic</i>	A receptor located before the connection of nerves (synapse) which influences the nature of the synapse.
<i>SANS</i>	Scale for the assessment of negative symptoms.
<i>Serotonergic</i>	Related to the neurotransmitter serotonin.

Second-generation antipsychotic medications are a heterogeneous group of medications that work at varying levels at many receptors, including dopaminergic, serotonergic, cholinergic, and histaminergic. Varying potencies at these receptors, and specific receptor subtypes, are responsible for not just the

antipsychotic and antimanic properties that these medications all share, but may also account for varying levels of anxiolytic effect. This article will explore some mechanistic answers for this anxiolytic effect including the effect on cortisol, decreased levels of akathisia compared to first-generation antipsychotic drugs, histaminergic effects, and increased potency at the serotonergic (5HT) 1A receptor.

Second-Generation Antipsychotic Drugs as Anxiolytic Agents in Animal Models of Anxiety

Initial efficacy for anxiolytic properties for antipsychotic drugs was controversial, but first observed in rat data. Bruhwyler et al. demonstrated that rats in an open-field paradigm had greater amount of exploration and decreased defecation while on high doses of clozapine. This was in contrast to the effect of haloperidol in a similar paradigm. Additionally, in an elevated plus-maze protocol, rats on a low dose of clozapine demonstrated behavior consistent with anxiogenic properties as they spent less time in the open part of the maze compared with rats who received only the vehicle injection.

Inoue et al. demonstrated that olanzapine and clozapine worked to prevent the acquisition of freezing, but not the expression of freezing, in a conditioned-fear paradigm. This was contrasted however with benzodiazepines, selective serotonin-reuptake inhibitors (SSRIs) and 5HT_{1A} antagonists which both inhibit the acquisition and expression of freezing. However, there was a slight separation from haloperidol and chlorpromazine in the response to the conditioned stimulus.

Further evidence of anxiolytic properties of second-generation antipsychotic drugs was shown in a conflict schedule model in which rats on olanzapine demonstrated similar behavior to those on chlordiazepoxide, but those on haloperidol and risperidone did not. In contrast, risperidone was shown to have short-term anxiolytic properties in a study by Nowakowska et al., however these effects were not seen after 7 days of treatment.

Akathisia – More Prevalent than it Appears?

Akathisia is a troubling side effect that is seen in upwards of 90% of younger patients treated with

first-generation antipsychotic drugs. In a mixed inpatient population, the rate of akathisia in patients on first-generation antipsychotic medications was 18% and pseudoakathisia was 24%. Though the prevalence tends to decrease with age, even in patients aged over 65 years, it is seen in up to 15% of patients.

These data are especially problematic as the core symptoms of akathisia are severe internal restlessness which generally leads to increased motor activity including pacing, marching, and ultimately can manifest as a severe dysphoria. Other common symptoms of akathisia include tension, panic, irritability, and impatience. Suicidality has been linked to akathisia in patients on high potency first-generation antipsychotic drugs. Akathisia is difficult for patients to describe subjectively and can, therefore, often be confused for anxiety. Patients who develop akathisia are also at a much higher risk for nonadherence to treatment and therefore are at a higher risk for relapse.

Second-generation antipsychotic drugs have shown a decreased rate of akathisia. This is considered to be related to the presynaptic blockade of 5HT_{2A} receptors which lead to increased levels of dopamine in the nigrostriatal pathway compared to first-generation antipsychotic drugs. In several trials, olanzapine has been shown to have decreased rates of extrapyramidal side effects including akathisia. In a large meta-analysis, olanzapine, risperidone, and placebo were shown to have decreased rates of akathisia compared with haloperidol.

In addition to the decreased rates of akathisia seen with second-generation antipsychotic drugs, there has been a benefit shown in treatment emergent extrapyramidal symptoms, including akathisia, when patients are switched from haloperidol to olanzapine. Costa e Silva et al. demonstrated an 83% decrease in akathisia symptoms, as measured by the Barnes Akathisia Scale, in patients switched from haloperidol to olanzapine in a large, multicenter trial in Latin America. It may be that some of the clinical observations of anxiety in patients taking first-generation antipsychotic medications is related to under diagnosed akathisia and that anxiolytic effects of second-generation antipsychotic drugs are related in part to the decreased rate of akathisia seen.

The 5HT_{1A} Receptor – an Anxiety Receptor for Antipsychotic Drugs?

The 5HT_{1A} receptor has long been associated with anxiolytic benefit. Buspirone is a partial agonist at 5HT_{1A} receptor and has been considered by many to be an anxiolytic agent. Atypical antipsychotic medications have varying degrees of activity at the

5HT_{1A} receptor, with the strongest affinity seen by aripiprazole and ziprasidone. 5HT_{1A} agonists do not typically occupy the receptor at clinically significant doses, but do alter the overall activity at the receptor. Aripiprazole, ziprasidone, quetiapine, and clozapine have been shown to have partial agonist activity at 5HT_{1A}, with aripiprazole and ziprasidone the most potent. 5HT_{1A} agonism has been linked to increased release of dopamine in the striatum, though it is not clear if this is clinically significant.

Ziprasidone has shown anxiolytic effects in non-psychotic individuals. In a double-blind, randomized trial (30 subjects), ziprasidone was compared to diazepam for anxiety prior to dental procedures. Ziprasidone showed a more rapid, and a slightly more potent, anxiolytic effect compared to diazepam which had a later onset and duration of action. Both were effective, with ziprasidone showing a lesser effect on blood pressure and not showing any greater sedation than placebo, compared to diazepam which was substantially sedating for over 2 hours.

Histamine – Antipsychotic Drugs as Soporific Agents

Histaminergic agents have long been used as treatments for anxiety and insomnia. Histamine antagonists, such as hydroxyzine, have been used as successful treatments in generalized anxiety disorder (GAD), and are often used in posttraumatic stress disorder (PTSD) and acute anxiety. Olanzapine and quetiapine are potent antagonists of the H₁ receptor. H₁ antagonists have also been shown to reduce the level of cortisol, which may be an indirect mechanism for achieving an anxiolytic effect. In this way, the antihistaminergic antipsychotic drugs share characteristics with some of the tricyclic antidepressant drugs, such as clomipramine and imipramine. Clomipramine, a highly histaminergic tricyclic antidepressant, remains one of the most powerful medications for obsessive-compulsive disorder (OCD) currently available. Recent work has identified antipsychotic drugs as useful in augmentation of OCD treatment. Risperidone has the most robust data, but there are reports regarding the use of quetiapine and olanzapine. Antipsychotic drugs have not shown benefit as monotherapy however, but in combination with serotonergic agents provide additional benefit in treatment refractory cases. The data for patients with comorbid tic disorders shows the most benefit from treatment with antipsychotic drugs.

Antipsychotic drugs are also being increasingly prescribed for insomnia. In patients with insomnia secondary to PTSD, olanzapine has shown a benefit as

an augmenting agent, targeting sleep and nightmares. There have been some initial studies regarding alpha-1 antagonists such as prazosin in decreasing nightmares associated with PTSD. Olanzapine and quetiapine are potent alpha-1 antagonists as well, and in that way may provide a benefit in treatment of nightmares and insomnia associated with PTSD. Additionally, the antihistamine properties of these medications also make them sedating and while that may be a treatment limiting side effect in certain circumstances, makes them beneficial agents in the treatment of sleep. Despite these benefits, caution should be exercised in using these medications solely for treatment of insomnia as there are many other treatment options and the side effect profile of these medications restricts their use to only the most refractory cases in which polypharmacy is needed.

Cortisol – How do Stress Hormones Respond to Dopamine Blockade?

Cortisol is a hormone that is typically associated as a biomarker for stress that has also been shown to be elevated in depression and anxiety. It is also been shown to be elevated overall in schizophrenia. A correlation has been seen between increased negative symptoms, measured by the Scale for the Assessment of Negative Symptoms (SANS), and elevations in cortisol, though overall psychopathology scores, medication dosage, and type of medication needed do not necessarily correlate with cortisol levels. Cognitive symptoms, often considered to be most predictive of future prognosis in schizophrenia, are also correlate severity with increased cortisol levels.

The worsened cognitive symptoms with hypercortisolemia may be related to long-term damage to the hippocampus that is seen with chronic elevations in cortisol. In the primate brain, high concentrations of glucocorticoid receptors are seen in the hippocampus and in the primates given chronic dexamethasone treatment, there is an approximately 30% reduction in size and segmental volumes of the hippocampus over time. Similar effects on the hippocampus are seen in primates exposed to animal paradigms of chronic stress. Schizophrenia patients, even at initial presentation, are known to have structural deficits of the hippocampus.

In a double-blind, randomized, cross-over trial, olanzapine and quetiapine showed decreased cortisol levels compared to haloperidol and placebo. The mechanism behind such a direct action on cortisol is not fully understood, but may be most prominently related to the action on serotonergic receptors, with some contribution from histaminergic or adrenergic

blockade. The decreased level of cortisol may relate to the antidepressant and anxiolytic action seen with these agents over the first-generation antipsychotic drugs.

Clinical Reports of Second-Generation Antipsychotic Drugs in Anxiety Disorders

The clinical literature on using antipsychotic medications for anxiety disorders is fairly limited. The mainstay of treatment are primarily the SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) and thus antipsychotic medications are typically used adjunctively when those medications are not fully effective. Other medications that are also utilized include benzodiazepines and antihistaminergic medications and buspirone. Atypical antipsychotic medications are overall used mostly as adjunctive agents in the treatment of refractory anxiety.

A double-blind, placebo-controlled trial of risperidone augmentation in GAD showed decreased core anxiety symptoms on the Hamilton Rating Scale for Anxiety. There have been several small, open label studies in GAD and social anxiety disorder that have had conflicting and ultimately inconclusive results. Risperidone, ziprasidone, olanzapine, quetiapine, and aripiprazole all have open-label studies associated with their use in refractory GAD, but thus far none have been demonstrated as effective monotherapy. While the data is scant, what can be surmised is that there is a subset of patients with severe GAD who are aided by these medications. Particularly, the medications that are most soporific will induce sleep and can be calming to the patients suffering from GAD. Further work and double-blind studies are needed to determine the ultimate clinical benefit from these agents.

In PTSD, atypical agents have most been targeted for their effects on sleep and insomnia. Nightmares and other intrusive thoughts are a common feature of this disorder and have been shown to be generally responsive to atypical antipsychotic drugs. In war survivors in Croatia, monotherapy with fluphenazine, risperidone, quetiapine, or olanzapine led to decreased symptoms of PTSD. The more sedating antipsychotic drugs have shown an increased benefit with promoting more restful sleep with the most data being shown for quetiapine. Other data have been shown in olanzapine and risperidone. Again, these agents have shown the most promise when used adjunctively to serotonergic antidepressants.

There are a number of articles in which antipsychotic drugs are used to control severe OCD symptoms, however, the paradox is that there are also a

number of articles suggesting that the atypical antipsychotic medications may worsen obsessive compulsive symptoms and even bring them on *de novo*. The thought is that the 5HT_{2A} antagonism is the mechanism by which the anxiety/OCD symptoms can worsen.

Future Directions

There is growing support and evidence that antipsychotic drugs may provide anxiolytic benefit for a variety of disorders – psychotic disorders as well as PTSD, OCD, and GAD. The future challenges we face in using this class of agents so broadly is to do so carefully, as there are many untoward side effects that are emerging, most concerning are diabetes, weight gain, and dyslipidemia. Chronic usage of atypical antipsychotic drugs requires close health maintenance and monitoring for subtle changes in metabolic activity. More rare side effects, such as neuroleptic malignant syndrome and dystonia, must also not be forgotten, as they are reported in all the atypical antipsychotic medications, though at frequencies that are less than the first-generation, high-potency agents. As the treatment of anxiety disorders has shifted more towards the primary care setting, education into the less common side effects is important in those prescribing these agents. Additional consideration must be made towards the relatively high cost of these medications compared to other alternatives. Atypical antipsychotic drugs do not characteristically show addictive potential, though there have been reports of diversion of quetiapine, particularly in the prison population. Overall, these agents do show promise, particularly for the refractory patient, and when used judiciously provide a helpful adjunct to therapy for severe anxiety disorders.

Neuroanatomical and Neurochemical Basis of Arousal

Amplified States of Arousal

Significance of Studying Arousal

Promising Future Lies Ahead in Arousal Research

Glossary

Arousal The fundamental property of the central nervous system that determines the amplitude of responses to any given stimulus.

Arousal crescent A group of primitive neurons residing in the ventral and medial edges of the brain stem that have ascending projections that alert the brain.

Arousal-promoting mechanisms Monoaminergic cell groups (dorsal raphe nuclei, locus coeruleus, substantia nigra and ventral periaqueductal gray, and tuberomammillary nuclei) that have ascending projections to the thalamus, hypothalamus, and cerebral cortex and whose chemical products favor states of behavioral arousal.

Sleep-promoting mechanisms A small group of neurons residing in the ventrolateral preoptic nucleus that fire predominantly during sleep and send inhibitory projections to the monoaminergic cell groups.

Arousal

Stress responses, whether defined endocrinologically or behaviorally, depend for their expression on the fundamental arousal of the central nervous system (CNS). The relation between stress and arousal is not simple. In terms of a person's psychological feelings, moderate and increasing levels of arousal can be a good thing. However, too much or for too long is both tiring and unpleasant (**Figure 1**).

In the workplace, the relationship between stress and arousal has been defined by occupational psychologists (**Table 1**). Too much demand with too little control can be so stressful as to cause illness. Therefore, it is useful to explore CNS mechanisms underlying the concept of arousal. Here we briefly summarize its operational definition, neuroanatomy, functional genomics, and neurochemistry.

Generalized Arousal

Although intuitively simple to understand, the concept of arousal has not been an easy one to define scientifically. Because all our behaviors and responses to stimuli depend on the underlying state of arousal we are in, it becomes critically important to quantitatively define arousal and to have ways to accurately measure it.

Arousal refers to the degree of stimulation necessary to drive a certain behavior in an animal. The particular stimulus or behavior can vary, but the underlying arousal state determines the magnitude of the response and even if the behavior will occur at all. Another way of envisioning this concept is that arousal is the force or motivation behind a given response, whereas the stimulus dictates what the response modality is.

The overall arousal state of an organism depends on generalized arousal and many specific forms of arousal, such as hunger, thirst, sex, sleep, and fear (**Figure 2**). If we express this concept in the framework of a mathematical equation, then arousal (A) is a function of the general arousal (A_g) state and each individual specific arousal component (A_{s1-n}). Influencing each of these variables is the underlying temperament of the individual, which we express as a constant (K) for each variable ($g, 1-n$). Because these parameters (thirst, hunger, sex, sleep, fear, etc.)

Figure 1 Prolonged arousal can lead to stress.

Table 1 Relationship between occupational demands and employee's control

		<i>Demand for arousal, alertness, and vigilance</i>	
		<i>High</i>	<i>Low</i>
Degree of control by employee	High	Stimulating	Boring
	Low	Stressful	Restful

Figure 2 Representation of the arousal equation. Each specific arousal (e.g., pain) depends on the underlying generalized arousal state of the animals, as well as on other specific arousal components (e.g., hunger motivation).

often influence one another, the Arousal Equation can quickly become very complex:

$$A = f(K_g A_g + K_{s1} A_{s1} + K_{s2} A_{s2} + \dots + K_{sn} A_{sn})$$

Traditionally, scientists studying arousal often disagreed on a definition of arousal. Some viewed arousal as one large behavioral phenomenon, where others viewed it as a collection of multiple specific components. The concept outlined in the Arousal Equation unifies, for the first time, these two schools of thought and provides a precise, experimentally feasible manner of determining the arousal state of an animal.

Operational Definition and Quantitative Measures of Arousal

Generalized arousal can be experimentally determined and measured. By definition, an animal is considered to be more aroused if it has increased responsiveness to stimuli (S) from the environment (any sensory modality), increased voluntary motor (M) activity, and also increased ability to react emotionally (E). These three components encompass large classes of varied sensory modalities, which invariably give us a better measure of generalized CNS arousal. This is in sharp contrast to classic neuroscience, which sought to characterize the specific responses of an organism to a specific stimulus. Behavioral arousal is produced by select brain pathways and key populations of neurons being activated, eventually leading to changes in gene-expression patterns.

Using a statistical test called principal components analysis has enabled us to screen large amounts of data (e.g., behavioral responses to the three modalities of stimuli – sensory, motor and emotional reactivity – for each mouse) and uncover trends in the data. The use of this mathematical tool has revealed that generalized arousal accounts for approximately

one-third (from 29.7 to 45%, depending on the experimental conditions) of all the data in arousal-related activities.

Application of Information Theory to Understanding the Neurobiology of Arousal

Introduced by Claude Shannon in the late 1940s, information theory, also known as Shannon's communication theory, establishes that the probability that an event will occur is inversely proportional to the information carried in that event. Consider, for example, the act of flipping a coin. There is a 50% chance of the coin landing heads up versus tails up; therefore, the possible information carried in this system is maximal – the more uncertain an outcome is, the more information transmittal there is. In contrast, if an event has a very high probability of occurring, there is very little room for doubt and very little information carried by the system. In neurobiological terms, the more unexpected the stimulus, the more dramatic the response (e.g., startle) will be. Likewise, the more nonintellectually stimulating environment, the less alert the animal will be and the less likely it is to respond to a stimulus (i.e., the less aroused it is).

Within the CNS, neuronal firing patterns are also governed by the principles of information theory. At any given time, there is a certain probability that a neuron will fire. The closer this probability is to 0.5 (or 50%), the more aroused the animal will be and the larger the repertoire of possible responses it can mount.

Neuroanatomical and Neurochemical Basis of Arousal

Proper arousal responses are critically important for nearly every aspect of our lives. Given this primal role, it is not surprising that nature has evolved ways to ensure that its regulation is safeguarded. This is accomplished by having multiple, redundant, and independent but cooperative mechanisms contributing to the overall arousal state.

Primordial Arousal-Promoting Neurons in the Arousal Crescent

A population of neurons in the reticular formation plays a key role in the regulation of arousal. These neurons originate in the ventral area of the brain stem, at the junction with the spinal cord, and extend bilaterally in a crescent-shaped form through the brain stem and eventually project ventrally into the thalamus and hypothalamus. This neuronal group is among the most evolutionarily conserved networks in animals, adding support to the hypothesis that it plays a crucial role in modulating arousal. These

neurons have a keen ability to sense and respond to a variety of arousing stimuli arising from within the body and the environment, including changes in blood pressure, pain, stress, and hormone levels. These neurons, mostly glutamatergic in nature, have ascending projections to the thalamus, hypothalamus, and basal forebrain, as well as descending projections to the spinal cord. These projections terminate at biologically relevant cell groups that are also involved in arousal control (e.g., the basal forebrain). Projections from this arousal crescent can travel via two routes: a ventral one and a dorsal one. The more ventral one is evolutionarily more primitive and terminates in the cholinergic basal forebrain. The more dorsal route terminates in the thalamus and hypothalamus and is more recent, evolutionarily speaking; it is especially well developed in primates.

Ascending Arousal Activating Pathways

In the 1940s and 1950s, Moruzzi, Magoun, and other neurophysiologists identified a key population of arousal-promoting neurons residing in the brain-stem reticular formation. These cholinergic neurons, found predominantly in the laterodorsal tegmental nucleus and the pedunculopontine tegmental nucleus, have extensive excitatory projections to the thalamus, which in turn project to widespread areas of the cerebral cortex. Acetylcholine release in both the thalamus and the cortex is highest during behaviorally aroused states of wakefulness and rapid eye movement (REM) sleep. In addition to the projections to the thalamus and eventually the cortex, brain-stem reticular neurons also project to the basal forebrain and hypothalamus, which contributes to stabilizing the aroused state.

Monoaminergic nuclei include the serotonergic dorsal raphe nuclei, adrenergic locus coeruleus, and dopaminergic substantia nigra in the brain stem, as well as the histaminergic tuberomammillary nucleus in the posterior hypothalamus. These nuclei all exhibit the highest discharge rates with maximal neurotransmitter release during wakefulness, lower discharge rates in non-REM sleep, and cease firing during REM sleep. The silencing of these neurons, and thus the absence of monoamine neurotransmission, plays a permissive role on REM sleep. These monoaminergic nuclei have ascending projections to the thalamus, hypothalamus, and cerebral cortex that favor states of behavioral arousal (e.g., wakefulness and REM sleep).

Descending Arousal Pathways

In antiphase to these arousal-promoting mechanisms, there are select brain regions that actively promote

cortical synchronization, characteristic of non-REM sleep. One such brain nucleus is the hypothalamic ventrolateral preoptic nucleus (VLPO), whose neurons send inhibitory γ -aminobutyric acid (GABA)ergic and galaninergic projections to the monoaminergic cell groups, thus silencing them.

The lateral hypothalamus also contains neurons that are important for vigilance control. Wake-active orexin-producing neurons have been shown to have excitatory projections to monoaminergic cell groups. Significantly, monoaminergic projections to the VLPO express orexin receptors, and the lack of orexin binding at these receptors causes behavioral state instability associated with narcolepsy. In addition, intermingled with these neurons are melanin-concentrating hormone–GABA-containing neurons that are most active during REM sleep.

Neurochemicals Influencing Arousal

Acetylcholine Originally called vagusstoff (in reference to its release after stimulation of the vagus nerve), acetylcholine was the first neurotransmitter to be discovered. It is produced by the enzyme choline acetyltransferase and can bind to two classes of receptors: nicotinic and muscarinic. The major sources of acetylcholine in the CNS are the basal forebrain, pontine reticular formation, and medial septum. Cholinergic neurons from the reticular formation provide a major excitatory input, stimulating cortical activation, and the discharge patterns of these neurons are highest during behavioral aroused states.

Noradrenaline/norepinephrine In the CNS, norepinephrine is primarily produced by the locus ceruleus neurons, and these neurons promote behavioral arousal, primarily via their projections to the forebrain, brain stem, and spinal cord. Like other monoaminergic cell groups in the brain, locus ceruleus neurons discharge maximally during active waking, decrease their firing rates during non-REM sleep, and are silent during REM sleep. Norepinephrine inhibits VLPO sleep-promoting neurons by binding at α_2 -adrenoreceptors. Also, significantly, norepinephrine increases the female sexual behavior lordosis by modulating the firing rates of ventromedial hypothalamic neurons, and sexual interactions between mice lead to increased norepinephrine release in the hypothalamus.

Serotonin Produced in the dorsal raphe nuclei of the brain stem, serotonin is a monoaminergic neurotransmitter that, like norepinephrine, promotes arousal. Serotonergic neurons fire maximally during waking (quiet waking), decrease their firing rate during non-REM sleep, and cease firing during REM sleep.

Many mood disorders, anxiety, and depression have been linked to deficiencies in serotonergic neurotransmission. Due to the large number of serotonin receptors (14) and their varied functions, studying the pharmacology of serotonin can be quite challenging.

Histamine Produced by tuberomammillary neurons in the posterior hypothalamus, histamine is a biogenic amine involved in vigilance control. With discharge patterns similar to serotonergic and noradrenergic neurons, maximal histamine release occurs during the waking state, and the administration of anti-histamines is often accompanied by drowsiness. Like norepinephrine, histamine also increases sexual behavior in female mice by increasing the firing rates of ventromedial hypothalamic neurons. In addition, sleep-promoting VLPO region neurons send inhibitory GABAergic and galaninergic projections to histaminergic neurons, thus establishing a mutually exclusive, reciprocal interaction between the arousal and sleep-promoting brain regions.

Dopamine Neurons containing dopamine in the ventral periaqueductal gray matter have recently been identified as a major dopaminergic input to modulate arousal. These neurons have the highest discharge rates during wakefulness and have extensive projections to brain regions involved in sleep regulation. Dopaminergic neurons from the ventromedial nucleus and the substantia nigra may also contribute to promote arousal.

Orexin/hypocretin The recently discovered neuropeptides orexin/hypocretin are produced by a small population of neurons in the lateral hypothalamus perifornical area. The two peptides have the same precursor protein and, in addition to playing a role in stimulating appetite, they promote wakefulness. Orexinergic neurons have direct excitatory projections to the tuberomammillary nucleus, and a deficiency in either the orexin peptides or the receptors leads to behavioral state instability and narcolepsy.

Prostaglandin D₂ Prostaglandin D synthase catalyzes the isomerization of the common prostanoid precursor prostaglandin H₂ to the endogenous somnogen prostaglandin D₂. The involvement of prostaglandin D₂ in sleep regulation has been studied for the past 25 years. In fact, it was among the first endogenous sleep-promoting substances to be identified. Prostaglandin D₂ is thought to be involved in homeostatic sleep regulatory mechanisms because animals that lack prostaglandin D synthase or prostaglandin D₂ receptor fail to exhibit a sleep rebound in

response to sleep deprivation. The somnogenic effects of prostaglandin D₂ are hypothesized to be mediated by the nucleoside adenosine, and infusion of prostaglandin D₂ into the subarachnoid space increases extracellular levels of adenosine.

Adenosine The nucleoside end product of energy metabolism, adenosine, has been shown to accumulate in a wake-dependent manner in the basal forebrain. The sleep-promoting effects of prostaglandin D₂ have been shown to be mediated by adenosine 2A receptors in the VLPO. Adenosine has been shown to disinhibit sleep-active VLPO neurons by blocking inhibitory inputs to these neurons and also by directly exciting these neurons. In addition, adenosine can inhibit wake-active neurons in the tuberomammillary nucleus. Interestingly, the most widely consumed arousal-promoting drug by humans, caffeine, works by blocking adenosine 2A receptors.

Steroid hormones Estrogens are produced by the ovaries and are secreted shortly before ovulation. The major role of estrogen is to prepare the female body for courtship, mating, and, eventually, maternal care. As such, estrogens modulate most of the neurochemicals and pathways mediating arousal to ensure that reproduction occurs. Examples are seen in cholinergic neurotransmission, in which estrogens not only increase the rate of acetylcholine synthesis but also increase the number of cholinergic receptors on target neurons. Similarly, estrogens increase the expression of genes involved in norepinephrine production and enhance the responses of dopamine and histamine. Conversely, the levels of the enzyme that produces the endogenous somnogen prostaglandin D₂ is decreased after estrogen treatment. In addition to the well-established roles of estrogens on sexual behaviors, there are many nonreproductive effects of estrogens on behavior, including anxiety, food intake, learning, memory, mood disorders, and sleep.

Integration of Signals

The neuroanatomical pathways discussed so far refer to mechanisms mediating arousal and sleep-wakefulness induction; there are also underlying circadian and homeostatic forces that determine when sleep can occur. The homeostatic drive for sleep, also known as process S, can be envisioned as an increased pressure that progressively gets larger the longer the animal is kept awake and that eventually reaches threshold levels, which trigger sleep. This mechanism is involved in modulating the day-to-day sleep distribution patterns, as well as sleep rebound in response to extended wakefulness. Homeostatic

sleep-regulatory molecules (e.g., prostaglandin D₂, adenosine, and nitric oxide) accumulate in a wake-dependent manner and eventually stimulate sleep. Also communicating with these effector pathways is the circadian component, which determines when, along the 24-h light–dark cycle, sleep and arousal are most appropriate. In fact, the suprachiasmatic nucleus, the circadian pacemaker, has many direct and indirect projections to both sleep-promoting and arousal-promoting brain regions and thus contributes to the fine-tuning of arousal.

Amplified States of Arousal

Sex and Fear

Given the elaborate symphony of mechanisms and chemicals underlying arousal regulation, we quickly come to the conclusion that critical biological functions must rely on it. One such function is reproduction. The propagation of the species, our ultimate goal, is intimately dependent on proper levels of arousal at the appropriate times. The primal function that estrogens have is to prepare the body for reproduction. As such, redundant mechanisms have evolved that ensure that, once the hormonal milieu is optimal and ovulation is near, females exhibit the behaviors that attract mates and result in fruitful copulation. Although conceptually ideal, this scenario does not always occur. Imagine, if you will, that the animals are exposed to a stressful stimulus or are in an unfamiliar place; it may not be feasible to invest time and energy in reproduction when they should be worried, really, about survival. This is, in fact, what the literature tells us occurs in rodents. In the protective shelter of a running-wheel cage or a home cage in our arousal-monitoring equipment, after estrogen treatment the animals exhibited increased arousal (e.g., increased running-wheel activity). However, when the animals were tested in an open field or placed in an unfamiliar cage, the arousal behavior was quickly replaced by fear, resulting in lowered responsiveness by the animal.

A fine line exists between which estrogen-mediated mechanisms are activated, depending on the environmental circumstances the animal finds itself; therefore, caution must be exercised when analyzing and interpreting such behavioral responses.

Significance of Studying Arousal

Arousal-related disorders affect people of all ages and genders. They comprise a wide spectrum of ailments, ranging from problems of vigilance control (e.g., narcolepsy) to hyperactivity disorders (e.g.,

attention-deficit hyperactivity disorder) and, in extreme cases, to devastating vegetative states, all of which can have detrimental and costly consequences.

Disorders of Reduced Arousal

Sleep disorders Forty million Americans are chronically affected by sleep disorders, and an additional 20–30 million report episodic sleep problems. Disorders of sleep range from the most common insomnias to sudden infant death syndrome to hypersomnias. Lack of research and adequate public education has led to a rising epidemic of sleep disorders, especially those associated with obesity (e.g., sleep apnea) and also to a chronically sleep-deprived society. Disorders of arousal mechanisms can be disastrous and costly, causing poor job performance, lack of attention in classrooms, and traffic accidents, all resulting from loss of vigilance.

Extreme hypo-arousal states The most extreme and devastating states in which arousal mechanisms are compromised can be seen in patients in vegetative, comatose, and stuporous states. Although the redundancy of neuroanatomical and neurochemical pathways minimize the possibility that this will occur, situations still exist in which the ability to be aroused is compromised. Only by understanding and characterizing these mechanisms can there be hope that someday it may be possible to stimulate certain key elements of this pathway (perhaps neurons in the arousal crescent) to reverse or ameliorate this condition.

Disorders of hyperarousal Cases of excessive arousal can be seen in patients suffering from attention-deficit hyperactivity disorder and posttraumatic stress disorder. Although they do not appear to be as debilitating as disorders of decreased arousal, being too aroused can interfere with a person's ability to function in society, for example, being able to learn in school or to focus at work. Likewise, the inability to repress unwanted detrimental memories in post-traumatic stress disorder can interfere with the healing process and the ability to resume normal activities.

Promising Future Lies Ahead in Arousal Research

Arousal mechanisms underlie all behavioral aspects of our existence. Although nature has done an astonishing job of ensuring that arousal mechanisms function optimally, as can be seen by the many independent but redundant pathways regulating arousal, situations still exist in which this system

is compromised. Only by knowing the intricacies of this regulation can researchers develop pharmacological and surgical therapies to reversing these problems.

The Selye Alarm Reaction
Selye and Reproduction
Stress and Implantation

Glossary

<i>Amenorrhoea</i>	Absence of a menstrual period.
<i>Anorexia nervosa</i>	Relentless pursuit of thinness.
<i>Anovulation</i>	Absence of ovulation.
<i>Blastocyst</i>	Development of embryo with an inner (embryoblast) and outer (later placenta) cell mass.
COS	Controlled ovarian stimulation, by e.g. FSH in order to develop more than one ovarian follicle.
CRH	Corticotropin-releasing hormone.

<i>Endometrium</i>	Inner mucous membrane of the uterus.
<i>flt-1</i>	VEGF receptor.
<i>GnRH</i>	Gonadotropin-releasing hormone.
<i>Gonadotropins</i>	Tropic hormones (e.g. LH and FSH) that stimulate gonadal growth, steroidogenesis and gametogenesis.
<i>Hypercorticism</i>	Increased concentration of cortisol.
<i>KDR/flk-1</i>	VEGF receptor.
<i>LH</i>	Luteinizing hormone.
<i>FSH</i>	Follicle-stimulating hormone.
<i>hCG</i>	Human chorionic gonadatropin.
<i>hFSH</i>	Human follicle-stimulating hormone.
<i>hLH</i>	Human luteinizing hormone.
<i>HPA</i>	Hypothalamic-pituitary-adrenal.
<i>Perinatal</i>	Around birth
<i>VEGF</i>	Vascular endothelial growth factor.

The Selye Alarm Reaction

In Knobil and Neill's *Physiology of Reproduction*, Ferrin defines stress "as the state in which the general adaptation syndrome has been evoked and in which

an increased demand requires the body to perform adaptive functions to re-establish normalcy" (2006: 2627). The three phases differentiated by Selye are the alarm reaction, the first phase in which the stressor affects the balanced system and then attempts to neutralize the stressor by catecholamine release; the second phase, in which the hypothalamic-pituitary-adrenal (HPA) axis acts to stabilize the situation by corticosteroid release; and, when this fails, the third and fatal stage.

Selye and Reproduction

The classic example of the Selye effect in reproduction is still observed when women develop amenorrhea on exposure to extremely violent and life-threatening situations, such as occurred during World War II. Corticotropin releasing hormone (CRH) inhibits gonadotropin-releasing hormone (GnRH) secretion in the hypothalamus, which leads to absence of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) production and then to ovarian quiescence. Simultaneously, hypercortisolism is established. A similar mechanism of an activated HPA axis may lead to amenorrhea among endurance athletes and young women suffering from anorexia nervosa. However, in a consultation room of an infertility clinic, the perception of stress among normally cycling subfertile women is quite different from what we just have described as the Selye effect. The frequently expressed position of subfertile couples is that stress is involved in their infertility. The proof of their conviction as expressed by their friends and described in popular magazines is in the frequently occurring observation that there is a causal relation between taking a long weekend abroad and the desirable pregnancy. "Doctor, how can we avoid stress before and during the *in vitro* fertilization treatment?" asked a couple who was infertile for 5 years.

Three randomized controlled intervention trials illustrate the present situation between stress and assisted reproduction. One study by Kemeter and Feichtinger is low powered and flawed by methodology (e.g. no notification of the allocation concealment, doubts about randomization method), Tarabusi et al. and de Klerk et al. used surrogate endpoints (measuring depression and/or anxiety). From these sparse data we may at least conclude that a relationship between stress as defined in those publications and a hard clinical outcome after assisted procreation has not been properly investigated.

Stress and Implantation

In De Kloet et al., evidence is presented that suggests that stress-related events that occur between conception

and the postnatal period can impact the offspring and permanently change their brains and behavior. The difficulties we encounter studying these processes and extrapolating from animal data to the human situation is illustrated by the fact that challenges that occur as early as ovarian hyperstimulation applied to facilitate blastocyst implantation may affect postnatal life.

Singleton pregnancies from assisted reproduction have a significantly worse perinatal outcome than nonassisted singleton pregnancies, although the prevalence of very low birth weight and very preterm birth is low. Very preterm birth is associated with later neuromotor and cognitive impairment, reduced school performance, and psychiatric morbidity. Young adults who are born very prematurely have different personality types than their term-born peers. This may be associated with an increased risk of psychiatric difficulties.

Subfertility cannot explain the risk of poor perinatal outcome after ovarian stimulation. Assisted reproduction is nearly always preceded by ovarian stimulation, in contrast to cryopreserved and thawed embryo transfer (ET). Because birth weight after cryopreserved and thawed ET is normal or even increased compared to control values, we might hypothesize that ovarian stimulation (with or without an IVF or intracytoplasmic sperm insemination procedure) is associated with low birth weight and might be considered a stress factor in the implantation process.

Blastocyst implantation is intimately associated with vascular permeability and angiogenesis. The vascular endothelial growth factor (VEGF) is a potent stimulator of these two processes. It has four isoforms in rodents, VEGF115, VEGF120, VEGF164, and VEGF188, which bind to the two tyrosine kinase receptors, flt-1 and KDR/flk-1. Our studies showed that VEGF120 and VEGF164 are highly expressed in the uterus. VEGF120, like VEGF164, showed a very distinct transcript signal and also exhibited a spatio-temporal distribution; the mRNA expression of VEGF, flt-1, and flk-1 correlates spatially and temporally with changes in angiogenesis and vascular permeability at implantation sites.

In our study, we tested the hypothesis that treatment with gonadotropins to induce controlled ovarian stimulation (COS) evokes a stress response, whose effects persist after conception. Adult female CD1 mice were treated with urinary human FSH (hFSH) and urinary human chorionic gonadotropin (hCG), recombinant hFSH and recombinant hLH, or with saline alone. The end point tested was the expression of VEGF120 during the mouse peri-implantation period. Urinary gonadotropic treatment caused lower levels of VEGF120, flt-1, and flk-1 mRNA levels, reduced the size of the embryo implantation site,

delayed implantation and prolonged the gestational period; both urinary hFSH and urinary hCG contributed to the adverse effects. Recombinant gonadotropin treatment did not alter any of the parameters studied. In addition, our recent gene-expression profiling study using microarray technology showed that urinary gonadotropins, but not recombinant gonadotropins, exerted differential effects on gene-expression patterns during the murine peri-implantation period.

The CRH system is another factor that is hypothesized to play a role systemically and/or locally in blastocyst implantation. Studies in rodents have shown that CRH expression is 3.5-fold higher in the implantation sites than interimplantation sites and that the injection of a CRH receptor 1 (CRH-R1) antagonist resulted in a 50–70% reduction in the number of implantation sites. Moreover, the administration of antibody against CRH inhibits the attachment of the blastocyst to the implantation site. The activation of CRH receptors during the implantation phase has been demonstrated in the human endometrium. We, therefore, tested in the same system whether the urinary and recombinant gonadotropins influence the CRH system during the mouse peri-implantation period. The levels of CRH and CRH-R1 expression were not influenced, suggesting that the CRH system is not involved in mediating the adverse effects of urinary gonadotropins on the implantation process.

The urinary gonadotropins did not show a significant effect on birth weight, but we observed a positive correlation between birth weight and length of gestation, suggesting that the longer period of gestation allowed time for the fetuses to compensate for the delayed growth and achieve comparable birth weights.

Glossary

<i>Coping responses</i>	Cognitive and behavioral responses mobilized in an effort to manage stressful transactions.
<i>Individual-response specificity</i>	The proclivity of an individual to respond to a range of challenges with a consistent profile of physiological activation.

The effects of stress are manifest in four distinct domains: physiology, behavior, subjective experience, and cognitive function. The physiological effects of stress include alterations in neuroendocrine, autonomic nervous system, and immune function and are of great interest to biomedical researchers because of their implications for disease. The behavioral manifestations of stress include aggressive responses, freezing, and displacement activities in animals; health-related behaviors such as smoking and alcohol consumption in humans; and deficits in the performance of complex tasks that are particularly relevant to public safety in areas such as transport and pollution control. Subjective experiences during stress include distress and feelings of dissatisfaction and anger, together with anxiety and depressive responses, which may contribute to psychiatric ill health. The cognitive manifestations of stress include alterations in information processing and attentional and memory functions, which can, in turn, influence performance and decision-making capability.

Stress effects are patterned both within and across these four domains. Attempts to single out a gold-standard measure that provides a consistent indicator of stress responses in all situations have proved unsuccessful. For example, research in the tradition initiated by Hans Selye has emphasized the hypothalamic-pituitary-adrenocortical axis and the output of corticosteroids as central elements of physiological stress responses. Although it is true that this pathway is very sensitive to stressors, it does not necessarily relate closely to other responses. Thus, differences in the stress-induced inhibition of immune responses with varying stressor predictability and controllability

have been found to be independent of corticosteroid responses. Particularly low levels of cortisol have been recorded in victims of posttraumatic stress disorder, suggesting that some manifestations of stress are independent of heightened adrenocortical function. Similarly, it is commonplace in human studies to find weak or negligible correlations between the magnitude of subjective distress and the activation of physiological indices of stress.

Several factors appear to be important in understanding these variations in stress effects. The first is that the pattern of change depends on the nature of the stressful experience and the coping responses mobilized to manage the situation. Thus, naturalistic studies of antagonistic encounters in animals have drawn a distinction between active behavioral responses involving fighting and escape that are associated with sympathetic nervous system activation and more passive conservation-withdrawal behaviors that tend to be linked with parasympathetic responses. At the level of subjective disturbance, depressed mood tends to be elicited by loss events and experiences, whereas anxiety is more characteristic as a response to threatening occurrences.

Second, stress effects vary in their time course and duration. Coping responses that are effective acutely may become maladaptive when stimulation is prolonged. Some important differences in responses emerge only with chronic aversive stimulation, whereas other effects only arise after stimulation is terminated. For instance, studies of human information processing have shown that performance may be maintained during stress exposure due to the exertion of additional effort and that only later manifestations of disturbance emerge. Chronic or repeated stimulation may lead to the failure of regulatory physiological feedback systems, with damaging consequences. Thus, research on socioeconomic status and stress responsivity indicates that differences across the social gradient are more apparent in rates of post-stress recovery than in the magnitude of acute biological responses.

When the implications of stress research for health and well-being are considered, the variations in response between individuals are striking. Two people exposed to the same threatening situation may differ substantially in the magnitude and duration of stress responses, and stress-related health problems may emerge in several contrasting ways both physically and mentally. Some of these variations result

from differences in temperament, social resources, and the effectiveness of the coping responses that the individual brings to bear on the stressful transaction. Others relate to differences in vulnerability, which may arise through both genetic and experiential factors. Genetic variations both in central neurotransmitter metabolism and in peripheral receptor sensitivity contribute to variations in biological response. Animal studies have shown that experiences early in life, such as gentle handling or maternal separation, are associated with decreases or increases in neuroendocrine responses to stressful stimulation in adult life. Clinical investigations of adult psychiatric disorder have uncovered variations in childhood trauma and abuse that sensitize the individual to subsequent stressful events.

Another relevant factor is individual-response specificity. Identified through research on acute psychophysiological responses, this is the tendency for some people to react with a consistent physiological response profile across a range of challenges. One person may be particularly responsive in terms of blood pressure and will show exaggerated blood pressure responses to a range of situations, whereas another is more responsive hormonally or gastrointestinally. Such variations may signal the existence of a special vulnerability or lack of resistance in a particular biological system. Background factors such as nutritional status, physical fitness level, age, gender, and socioeconomic status all serve to moderate the extent to which stress responses may have long-term adverse effects. Hence, the prediction of stress effects in any particular case depends not only on assessing the responses in the four domains with appropriate measures but also on understanding the background factors that predispose to poor adaptation or alternatively bolster the individual's resilience.

Life Stress in Psychopathology
Generation of Stressful Life Events
Generation of Stress Perceptions and Threat
Issues in Stress Assessment

Glossary

<i>Appraisal</i>	A cognitive process that involves evaluating the degree of threat associated with a life stressor, as well as the implications of that stressor.
<i>Camberwell life events and difficulties schedule</i>	An interview-based procedure for evaluating the presence, severity, and origins of stressful events and difficulties.
<i>Diatheses</i>	Vulnerability factors that increase the stressfulness and negative consequences of life events.
<i>Difficulties</i>	Ongoing stressful situations that persist for at least 3 months.
<i>Independence</i>	The degree to which a person's behavior or characteristics might have brought about a stressful life event.
<i>Matching events</i>	Acute major negative events that arise from or are thematically related to ongoing chronic stressors or role conflicts.

Life Stress in Psychopathology

Links between life stress and mental disorders such as depression have been drawn throughout history. For example, in the seventeenth century Robert Burton described how melancholia often was precipitated by environmental adversities, including interpersonal losses. Indeed, the very phenomenology of depression involves feelings of loss and ruminations on the hopelessness of one's life situation. When depressed, one experiences the world as impoverished and as imposing impossible demands. In such a frame of mind, ordinary hassles become insurmountable obstacles, deprivations, or failures over which people despair.

Thus, depression itself magnifies the apparent stress and strain of life.

Investigators have typically examined the role that life stress might play in the onset and maintenance of mental disorders. In other words, the focus has been on how life stress can result in psychopathology. However, it is also clear that life stress often results from individuals' behavior or characteristics. Many stressful life events and difficulties, therefore, are not random occurrences that happen to befall the unfortunate, but rather are at least in part created by the same individuals who suffer from them.

Likewise, certain individuals tend to react to negative life events with greater feelings of stress and distress than others. Increasingly, investigators are exploring the manner in which characteristics of the person and the environment can breed stressful life events and difficulties, as well as the more subjective stress reactions to those events. This generated stress, in turn, potentially contributes to other adverse psychological outcomes, such as episodes of depression. Although this is largely studied in the context of depression, an important area of future research involves determining whether other forms of psychopathology also contribute to stress generation.

As suggested earlier, stress generation can involve two separate processes. First, characteristics or behavior of the individual can contribute to the occurrence of actual life events. In other words, for various reasons, some people are more prone to encountering negative life events and difficulties than others. Second, characteristics of the individual can contribute to the level of threat or perceived stress associated with particular life events. In other words, given seemingly identical life events, some people will experience more severe subjective stress reactions than others.

Generation of Stressful Life Events

It is clear that people tend to select or even forge environments that reflect their personalities and genetic predispositions. Individuals with various temperaments create social-environmental niches that are consistent with these characteristics, and in turn these environments are likely to be associated with various types of life events. For example, studies have demonstrated that persons with higher levels of the personality characteristic neuroticism are more prone to experiencing negative life events, whereas those who are higher in extroversion are more prone to experiencing positive life events. Likewise, it is

quite possible that cognitive diatheses associated with depression, such as negative attributional styles or dysfunctional beliefs about interpersonal relationships, can lead to future stressful life events. For example, an individual who is cognitively biased to interpret ambiguous social encounters as rejection is likely to create the very abandonment so feared. The person's negative interpretations are likely to lead to conflict and rejection. In a similar vein, there is strong evidence that individuals genetically predisposed to depression are at heightened risk for negative life events. For example, the nondepressed biological relatives of depressed persons have been shown to be at greater risk of experiencing major life stressors than relatives of nondepressed individuals. Several quantitative behavioral genetic studies have confirmed this genetic contribution to stressful life events. Overall it is apparent that negative life events are not entirely randomly distributed and, instead, tend to cluster in certain persons. Furthermore, these individuals seem to be the same persons who are most vulnerable to psychological disorders, particularly depressive episodes, following life stress.

Brown and colleagues were among the first to explore the role that psychiatric symptomatology might play in generating stressful life events. Initial efforts by this research team were directed at establishing that negative life events could play a causal role in the development of subsequent depressive episodes. It was therefore critical that these investigators focused on events that clearly arose independently of psychiatric symptomatology. Across a number of studies, these and other researchers demonstrated that major acute stressful life events that were independent of depression itself (as opposed to events such as hospitalization for depression or losing one's job because of concentration difficulties) contributed to the onset of episodes of this disorder. However, these investigators also established that individuals with subclinical depressive conditions, as well as other psychiatric conditions, were at greater risk of encountering environmental adversities than those who were without symptomatology. In other words, individuals with subclinical depression or other psychiatric conditions were more likely to be faced with major acute stressful life events than were asymptomatic individuals. These acute stressors, in turn, were associated with the onset of episodes of clinical depression. Interestingly, subclinical depression and other psychiatric conditions failed to predict future depressive episodes in the absence of life stressors. Apparently, stress generation was largely responsible for the exacerbation of depressive symptoms, leading subclinical experiences to develop into full depressive episodes.

Furthermore, subclinical depression and other psychiatric conditions were associated with the generation of life events that are particularly depressogenic. Specifically, these conditions bred acute life events that matched either ongoing life difficulties (e.g., a conflictual marriage) or role conflicts (e.g., a conflict between one's career and family). These types of matching events have proven to be extremely potent contributors to the onset of episodes of clinical depression. In other words, matching events seem to be considerably more likely to result in clinical depression than other types of negative life events. Unfortunately, depression-prone individuals appear to generate the very types of stressors that are most likely to exacerbate their psychiatric conditions.

In a highly influential paper, Hammen also suggested that stress generation might be an important mechanism through which depression can lead to future depression. Across a number of studies based on adult, adolescent, and child samples, Hammen and colleagues have demonstrated that depression-prone individuals experience a greater frequency of subsequent life stressors compared to those with other psychiatric conditions, those with medical illnesses, and healthy control participants. Interestingly, this research suggests that interpersonal stressors, in particular, are generated by depression-prone individuals. Interpersonal stressors largely include conflicts and tension between people. Importantly, Hammen's work has demonstrated that stress generation can take place even during periods of remission, suggesting that factors beyond depressive symptomatology itself are likely to be at work. In other words, stress generation appears to be driven by some correlate or correlates of depression rather than depressive symptomatology itself.

What might these correlates be? Studies have explored aspects of personality pathology and interpersonal functioning, such as poor interpersonal problem solving and excessive reassurance seeking. For example, symptoms of cluster A (odd and eccentric) and cluster B (dramatic and erratic) personality pathology have been found to contribute to the generation of interpersonal stress, which in turn predicted the development of depressive symptomatology. Other research has focused on two personality styles implicated in vulnerability to depression, sometimes referred to as interpersonal relatedness (a style marked by excessive dependence on relationships) and self-definition (a style marked by excessive reliance on achievement and individuality in maintaining self-esteem), and has found that self-definition is particularly related to stress generation. In terms of interpersonal functioning, one study found that the generation of minor social stressors mediated the association between excessive

reassurance seeking and the development of depressive symptoms, whereas another found that the generation of interpersonal stressors mediated the association between poor interpersonal problem solving and subsequent depressive symptoms. Another line of research conducted by Kendler and colleagues has found that neuroticism and genetic liability to depression contribute to stress generation, whereas childhood sexual abuse and variation in the serotonin transporter gene increase individuals' sensitivity to the depressogenic effects of life stressors. Together, these studies suggest that personality pathology, interpersonal functioning, and some forms of genetic liability are associated with future depression by increasing the likelihood that individuals encounter stressful life events (particularly interpersonal stressors), whereas traumatic stress early in life and other types of genetic variability increase stress sensitivity. It will be important for future work to determine whether these characteristics contribute to stress generation and sensitivity on their own, or whether their effects become more potent in combination with pre-existing depressive symptomatology.

In addition to these characteristics of the person, it is likely that characteristics of the person's social environment are also related to stress generation. Brown and colleagues have documented how other ongoing aspects of the social world are associated with risk for future acute life events. These investigators developed the concept of life structure as being important in understanding the origins of life stress. In many cases, individuals who are faced with various forms of deprivation during childhood (e.g., parental loss, abuse, or neglect) become locked into an ongoing conveyor belt of environmental adversity and psychological vulnerability. These childhood environmental experiences put individuals at risk for further negative environmental experiences during later stages of life. For example, parental lack of care, neglect, and abuse during childhood can lead to teen pregnancy and marriage to an undesirable partner. In turn, these experiences set the stage for a variety of additional acute stressful life events and difficulties that are likely to occur in the future, such as marital violence, economic hardship, and infidelity. Simultaneously, this conveyor belt of adversity would continuously foster and reinforce psychological vulnerabilities, such as feelings of helplessness and low self-esteem, making it increasingly difficult to cope with stressors.

In summary, acute negative life events are more likely to be encountered by individuals with certain characteristics. In particular, this type of stress generation is associated with some forms of genetic predisposition, neuroticism, depression, and, quite

possibly, cognitive characteristics that are thought to increase risk for depression. Further, these generated life events appear to be characterized by interpersonal conflict and a resonance with other ongoing life stressors or role conflicts. It is presently unclear why depression-prone individuals are at risk for generating life stress. Important directions for future work include examining theoretically plausible mediators and moderators of this effect. For example, Hammen and colleagues have begun to explore the possible roles of interpersonal functioning, comorbidity, and personality pathology, while Brown and colleagues have focused on the individual's unfolding social-environmental context. Future work also needs to examine stress generation in psychological disorders beyond depression.

Generation of Stress Perceptions and Threat

Individuals differ in the degree to which they experience negative reactions to seemingly identical life events, i.e., stress reactions are determined not only by the nature of the event, but also by the nature of the individual. Lazarus and Folkman proposed that stress itself is best thought of as a process in which the individual actively mediates the relationship between life events and psychological distress. In response to a life event, individuals are thought to first engage in a primary appraisal of the potential negativity or threat. Different individuals are likely to appraise the same event in quite different ways. One person may view a job demotion as an irreversible career blemish, while another may view this event as only a minor setback. Subsequent to this initial threat appraisal, individuals are thought to engage in another assessment. This secondary appraisal involves further evaluation of the situation and the degree to which the person has the resources available to effectively deal with the event. In a number of ways, this involves cognitive, emotional, and social aspects of the individual. Finally, following primary and secondary appraisal, different coping strategies can be initiated. Individuals are known to differ in their coping efficacy and typical coping styles, both of which are likely to effect psychological adjustment to life stress. In describing this stress process, Lazarus has been influential in identifying multiple ways in which properties of the individual can affect vulnerability to life stress.

Lazarus' model highlights the importance of individual differences in appraisal processes as contributing to the generation of stress reactions, but what underlies and influences these appraisals? From a theoretical perspective, other types of vulnerability

(so-called diatheses) may contribute to these negative appraisals. Diathesis stress models posit that certain characteristics increase the stress that individuals experience in response to negative life events. One such vulnerability factor that has received empirical support is attributional style.

According to Abramson and colleagues, individuals are motivated to understand and make sense of the causes of life events and tend to have relatively stable characteristic attributional styles. Persons who attribute negative life events to causes that are global (i.e., have far-reaching implications), stable (i.e., are predictive of future negative events), and internal (i.e., are caused by the self) are more likely to experience psychological distress than individuals who attribute negative life events to causes that are specific (i.e., are limited in life domain), unstable (i.e., are not likely to occur again), and external (i.e., are caused by the environment). While this is true of negative events, the opposite pattern is considered dysfunctional in the context of positive life events.

In addition to negative attributional styles, rigid, inappropriate, and perfectionistic beliefs about the self and the world, known as dysfunctional attitudes, likely contribute to the generation of stress perceptions and threat. Many of these beliefs concern contingencies of self-worth that are unrealistic in nature (e.g., one must be perfect or admired by all in order to be a person of worth or deserving of love). These cognitions are thought to interact with life stressors to result in psychological disorders. In this sense, a negative life event may be experienced as distressing in itself, but may also be considered by the individual to be an indication of a lack of self-worth. Through these beliefs, an event such as being laid off due to a factory closing may become a sign of one's personal incompetence and lack of value, generating more negative appraisals and perceived stress than would be generated by someone without these dysfunctional beliefs. In this way, the manner in which an individual's self-esteem is maintained and structured influences how much perceived stress is generated by particular classes of negative life events.

It is also apparent that environmental factors can contribute to these appraisal processes and, consequently, to the degree of stress generated by the occurrence of negative life events. For example, individuals with inadequate social support are likely to have more severe stress reactions than those with more supportive close relationships. Brown and colleagues have found that individuals who were "let down" during the negative event itself were more likely to develop episodes of depression than those who received expected crisis support. In the former situation, individuals' positive expectations about their close relationships would be shattered, leading to disappointment and

a reevaluation of the nature and quality of these relationships. Consequently, the event and its surrounding context would likely be appraised as considerably more threatening than if support had been forthcoming.

Likewise, individuals who are already faced with significant life stressors, particularly severe ongoing difficulties, are more likely to suffer from more severe stress reactions in response to additional negative life events than those without these additional burdens. Making matters more complicated, Coyne and Wiffen have argued that it is likely that these environmental factors are closely associated with the cognitive vulnerabilities discussed previously. For example, to some extent attributions about the implications of negative interpersonal events or dysfunctional beliefs about relationships likely arise from conflictual interpersonal relationships, such as unstable marriages. It becomes less clear whether it is primarily the cognitive characteristic (e.g., negative attributional style or dysfunctional beliefs about relationships) or the environmental factor (e.g., conflictual marriage) that contributes to the generation of stress reactions following an acute negative life event (e.g., a major argument with one's spouse).

In summary, characteristics of the individual and his or her social environment contribute to the degree of stress and distress that is generated in response to negative life events. These characteristics include appraisal processes that, in turn, are likely to be driven by underlying cognitive diatheses (such as negative "attribution styles" and dysfunctional beliefs), as well as environmental characteristics (such as inadequate social support and chronic stressors). An important area of future investigation involves attempting to disentangle the overlapping roles of these cognitive and environmental characteristics.

Issues in Stress Assessment

The notion of stress generation mandates that careful attention be paid to a number of issues in the assessment of life stress. First, it becomes crucial to examine the dimension of event independence. Presumably, generated events are those that were at least somewhat dependent on the individual's behavior or characteristics. Second, as previously discussed, stress generation involves two different processes: the first reflects the generation of actual negative life events, whereas the second reflects the generation of stress perceptions and reactions. Assessment procedures must be able to distinguish between these two processes. Third, it is becoming clear that in terms of objective events, stress generation is specific to certain classes of events, namely, events that match ongoing problems or that involve interpersonal

conflict. Assessment procedures need to be able to cleanly distinguish these classes of events from others.

In contrast to the stress generation studies conducted by Brown, Hammen, and their colleagues, the vast majority of research on the role of life stress in depression has relied on self-report checklists to assess life events. Unfortunately, self-report measures of life stress likely combine both relevant and irrelevant aspects of the stress construct, making it difficult to advance knowledge in this area. First, self-report measures of life events are unable to partition the occurrence of objective life events from the perception of life stress. As a result, it is unclear whether a participant's score is the result of actual changes in the environment or the perception of changes. A second major limitation of self-report life event measures is that they are unable to assess the degree to which events were influenced by the person or by other independent causes. Clearly, in order to investigate the hypothesis that individuals contribute to their own stress, it is necessary to establish that a given stressor was the result of an individual's behavior and was not completely independent or random. Finally, self-report measures make it difficult, if not impossible, to classify events into particular domains (e.g., interpersonal and matching versus nonmatching) in order to examine specific types of events.

Importantly, Hammen and colleagues' work suggests that depression generates interpersonal conflict events, but not other types of events. As such, these interpersonal conflict events should be examined separately from other types of events. It is notoriously difficult to make these distinctions on the basis of self-report checklists. For example, events that seemingly reflect noninterpersonal experiences (such as loss of one's job) often can involve an interpersonal conflict (such as a fight with one's boss). More in-depth probing is required to determine whether or not an event had significant interpersonal overtones.

Clearly, advancements in this area of inquiry are going to require the use of more sophisticated interview-based procedures that can more cleanly assess particular dimensions and domains of stressful life events. The Camberwell Life Events and Difficulties Schedule (LEDS) is the most well-developed and methodologically sound system. The LEDS first involves careful questioning about potential events in a variety of different life domains, as well as in-depth probing about the context surrounding each event. Events are then rated on a number of dimensions, including threat and independence, by a team of individuals who did not conduct the interview and who are kept blind to the psychological reactions to the events. In order to evaluate the likely individual meaning and importance of the event, ratings of degree of threat (stress) are made on the basis of the context

surrounding the event. So, for example, a pregnancy would be rated quite differently if it occurred in the context of a happy marriage and good financial resources than it would if it occurred in the context of marital violence, financial hardship, and poor living quarters. Of particular importance is the fact that the LEDS includes more than 5000 examples of different events that help anchor ratings of threat and independence. In addition, guidelines are provided to help determine what counts as an event. These guidelines set thresholds for inclusion and exclusion. Consequently, they help prevent individuals who report a number of very minor and trivial incidents from receiving higher scores than those who experienced the same incidents, but who failed to mention them during the interview. The LEDS is currently the only interview that includes these important features.

The notion of stress generation implies that the stressful life event in part resulted from the person's behavior or characteristics. As such, it is crucial that the dimension of life event independence is examined. The LEDS classifies events on a 12-point scale that includes categories that vary in terms of their independence of the person's behavior. Point 1 refers to events that are completely independent, such as accidents occurring to family members; point 2 refers to events for which it is impossible to completely rule out some aspect of the subject's behavior in leading to the event, e.g., a close friend deciding to move to another city; point 3 refers to events that possibly arose through the subject's behavior, but is unlikely, e.g., a child's academic difficulties; point 4 refers to physical illnesses of the subject; point 5 refers to events in which the subject consented or complied with external circumstances, e.g., agreeing to care for a sick relative; point 6 refers to intentional acts of the subject, e.g., deciding to return to school; point 7 refers to events that probably arose as a result of the subject's negligence, e.g., an automobile accident while subject was intoxicated; point 8 refers to events involving arguments or breaking off contact with someone after tension; point 9 refers to breaking off contact with someone without a precipitating argument or period of tension; point 10 refers to the subject's love events; point 11 refers to the subject's partner's love events, e.g., a partner's affair; and point 12 refers to events that are clearly the result of depression, e.g., fatigue, irritability, and concentration problems contributing to reprimands from one's boss and, eventually, to being fired.

In summary, research is beginning to document the ways in which individuals prone to psychological disorders, particularly depression, contribute to the stress that they experience in their lives. In turn, this generated stress might effect the onset, maintenance,

and recurrence of these conditions. Our developing understanding of these complicated transactional pathways suggests that more refined evaluations of life stress are required to advance knowledge in this area. In-depth interview-based approaches, such as the LEDS, are required to evaluate life events in terms of their severity, independence, content, and relation to other ongoing life problems.

Conclusion

Glossary

Maternal deprivation

Separation of mother and infant during the stress hyporesponsive period, which needs to last for at least 8 h for immediate and persistent effects on the neuroendocrine regulation of the hypothalamic-pituitary-adrenal axis.

Stress hyporesponsive period (SHRP)

A period of reduced adrenal corticosterone and pituitary adrenocorticotrophic hormone release in response to stress, lasting in the rat from postnatal day 4 to 14 and in the mouse from postnatal day 1 to 12.

Based primarily on the pioneering work of the late Hans Selye, the stress response has become somewhat synonymous with the release of hormones from the pituitary and the adrenal glands. Thus, in most adult mammals stimuli presumed to be stressful result in a systematic release of adrenocorticotrophic hormone (ACTH) and the subsequent secretion of glucocorticoids from the adrenal. This simplistic view of the pituitary-adrenal axis as first described by Selye has been elaborated on extensively. The regulation of the stress hormones clearly involves specific peptides synthesized and stored in the brain, corticotropin-releasing factor (CRF) and arginine vasopressin (AVP), and brain-derived neurotransmitters, such as norepinephrine. Thus, the brain must be included as a critical stress-responsive system. However, the sequences of responses observed consistently in the adult are in many ways very different in the developing organism. Abundant evidence indicates that the rules that govern the activity of the hypothalamic-pituitary-adrenal (HPA) axis in the adult are very different in the neonate.

Stress Hyporesponsive Period

In 1950, a report appeared that first indicated that the neonatal response to stress deviated markedly from that observed in the adult and thus created a field of inquiry that has persisted for over 4 decades. Using changes in adrenal ascorbic acid as the response to stress, Jailer reported that the neonate did not show any response to stress. By the early 1960s, Shapiro placed a formal label on this phenomena, designating it the stress nonresponsive period (SNRP). It is important to note that for the most part the database for this description was the inability of the rat pup to show significant elevations of corticosterone following stress. There was one study that received little attention at the time but did raise important questions concerning the validity of the notion of an SNRP. In that study, in addition to exposing the pup to stress and its demonstrating a lack of a corticosterone response, another group was injected with ACTH. These pups also failed to elicit a corticosterone response, which indicated that one of the factors contributing to the SNRP could be a decreased sensitivity of the adrenal to ACTH. Therefore, it was conceivable that other components of the HPA axis might be responsive to stress. The resolution of this question was dependent on the availability of relatively easy and inexpensive procedures for examining other components of the HPA axis. The methodological break through, which altered most of endocrinology and had a major impact on our understanding the ontogeny of the stress response, was the development of radioimmunoassay (RIA) procedures.

The initial impact of the RIA was to change the designation of this developmental period for the SNRP to the stress hyporesponsive period (SHRP). This change was a result of studies that showed a small but significant rise in corticosterone when measured by the RIA. Thus, although the response of the adrenal was reduced markedly during the SHRP, the adrenal was capable of releasing low levels of corticosterone.

It has been argued that the biological function of the SHRP is to protect the developing organism, specifically the brain, from an excess of circulating glucocorticoids. There is abundant evidence that high levels of glucocorticoids suppress neural growth; thus, under basal circumstances, it seems beneficial for the neonate to suppress the activity of the stress system. However, in situations that threaten health or even survival, an activation of the HPA system might be crucial. The HPA axis during development is unique in that it maintains a delicate balancing act between the regulation of stable levels of corticosterone and the ability to respond to systemic stimuli that may be life threatening. Thus, the neonate can more precisely discriminate between stressors that require higher-level cognitive processing and life-threatening events.

Indeed, when investigators began to examine other components of the neonate's HPA axis it became apparent that the SHRP was by no means absolute and that the different components of the axis responded differentially and were stimulus-specific. The question addressed in this article is whether the concept of the SHRP is still valid. In order to confront this question, we examine the development of several components of the HPA axis: the adrenal, the pituitary, and the brain.

Stress Hyporesponsive Period, the Adrenal, and Corticosterone

This article focuses on how the development of the different components of the HPA axis bears on the issue of the SHRP. It is generally agreed that in response to most stressors the neonate fails to elicit adrenocortical response or does so minimally. There are several features that characterize the function of the pup's adrenal. The first and most obvious characteristic of the adrenal is that basal levels of corticosterone during the SHRP are considerably lower than observed immediately following parturition and after the pup emerges from the period of adrenal quiescence, which is normally between postnatal day 4 and 14 in the rat (postnatal day 1 and 12 in the mouse). Further, numerous investigators have reported that the neonate can elicit a significant increase in plasma levels of corticosterone following a variety of challenges. However, invariably the

magnitude of the response is small compared to older pups that are outside the SHRP and, of course, to the adult. Thus, whereas the reported changes in corticosterone levels following stress in the adult can at times exceed $50 \mu\text{g dl}^{-1}$, rarely does the infant during the SHRP reach levels that exceed $10 \mu\text{g dl}^{-1}$. These levels are reached only under special circumstances. Thus, the ability of the neonatal adrenal to secrete corticosterone seems to be impaired markedly.

There is an important caveat in making the assumption that the reduced level of corticosterone following stress indicates a reduction in biological activity. Corticosterone exists in the circulation in two forms, bound and unbound. The large majority of corticosterone in the adult is bound to corticosteroid-binding protein (CBG) and other binding proteins. Only a small fraction exists in the free form, which is considered to be the biologically active form. Another aspect of the SHRP in rodents is the relative absence of CBG during the SHRP. Thus, although absolute values of corticosterone, which normally include both bound and unbound hormone, are very low in the absence of CBG, the fraction of corticosterone that is available in the free form for binding to corticosteroid receptors may actually be higher than is observed in the adult. Further, the clearance of corticosterone from the circulation is significantly slower in the pup and, as a consequence, corticosterone is available for a more prolonged period. Thus, the biologically active corticosterone does have a more prolonged time to exert its effects in the periphery and the brain.

Although there appear to be rate-limiting factors that act developmentally to limit the secretion of corticosterone in the neonate, evidence indicates that the adrenal is actively suppressed during the SHRP. It has been extensively documented that certain aspects of the rodent maternal behavior play an important role in regulating the neonate HPA axis. In particular, two specific components of the dam's caregiving activities seem to be critical; licking/stroking and feeding. Numerous studies have demonstrated that feeding is in part responsible for the suppression of the pup's capacity to both secrete and clear corticosterone from the circulation. Thus, removing the mother from the litter for 24 h (and thus fasting the pup) results in a significantly higher basal level and a further increase in the secretion of corticosterone following stress or administration of ACTH. The initial activation of the HPA axis occurs after between 4 and 8 h of maternal absence. This process is likely mediated by metabolic signals because replacement with glucose or blockade of ghrelin receptors during deprivation prevents HPA axis activation. We have postulated that one of the consequences of maternal

deprivation is to increase the sensitivity of the adrenal to ACTH. This has been demonstrated in several ways. (1) Following deprivation, significantly lower doses of ACTH are required to induce the adrenal to secrete corticosterone. (2) Although the levels of ACTH are equivalent between deprived and non-deprived pups under certain experimental conditions, the levels of corticosterone are greater in deprived pups. (3) Studies indicate that following a mild stress (injection of isotonic saline) there is an increase in *c-fos* gene expression in the adrenal cortex of the deprived neonate, whereas the nondeprived pup exhibited almost no detectable levels of *c-fos* mRNA. If maternally deprived pups are provided with food during the period of maternal deprivation, both basal and stress levels of corticosterone no longer differ from mother-reared pups.

Stress Hyporesponsive Period and the Pituitary

The concept of an absolute SHRP regarding the response of the pituitary following stress in the neonate is much more problematic. Whether the pituitary can show an increase in ACTH in response to stress is dependent on numerous factors. Among these are the age of the neonate, the type of stress imposed, and, once again, maternal factors. The early findings concerning the stress response of the pituitary suggested that there was a deficiency in the neonate's capacity to synthesize ACTH. Thus, as a result, the pup should exhibit a reduction in the magnitude of the ACTH stress response. However, sufficient data indicate that the pituitary of the neonate does have the capacity to synthesize and release ACTH that closely resembles the adult response. What seems to discriminate the neonate from the adult is that for the pup the response of the pituitary is much more stimulus-dependent. Further, the ability to terminate the stress response is also not fully developed and does not mature until quite late in development. Perhaps the earliest demonstration that the neonate can indeed mount an ACTH response to at least some types of challenges was a study that challenged neonates with an injection of endotoxin throughout the period from birth to weaning. At all ages, the neonate exhibited a significant elevation of ACTH that, beginning day 5, was equivalent to the adult. Of interest is that, although there was a robust ACTH response, the corticosterone response was reduced markedly from day 5 and did not begin to approach adult value until approximately day 15. The difficulty with this study is that very large doses (90% lethal dose, LD90) were used. It has been reported more recently that

the administration of interleukin (IL)-1 elicited an ACTH response in pups as early as postnatal day 6. The peak of the response followed a similar time course to that of the adult, although the magnitude of the response was significantly lower early in development. The reduced response in day 6 neonates cannot, however, be interpreted as a reduction in the neonate's capacity to produce ACTH. Three hours following adrenalectomy (ADX), a robust increase in ACTH occurs as early as day 5, presumably due to the absence of a corticosterone negative feedback signal. This magnitude of the ACTH response is as great as that seen in older neonates at day 18, which are well out of the SHRP. Under some circumstances, the pup can show an even greater ACTH response early in development than later. In contrast, brief periods of maternal separation, exposure to novelty, injections of isotonic saline, and restraint for 30 min all failed to elicit an ACTH response in normally reared pups until they escaped from the SHRP.

Recent studies in the mouse have revealed that the low and suppressed ACTH response during the SHRP is largely mediated by an enhanced glucocorticoid receptor (GR)-mediated negative feedback. Treatment with the GR antagonist RU486 resulted in a pronounced increase of basal ACTH and corticosterone values in 9-day-old pups to levels greater than in the adult (see Figure 1). As a different study observed, because only a small effect of RU486 is observed when it is applied locally at the paraventricular nucleus (PVN), a direct GR-mediated suppression of ACTH production and release at the pituitary level seems likely, at least toward the end of the SHRP. These data also indicate that the hypoactivity of the neonatal stress system may be restricted to the pituitary-adrenal axis.

However, so far there is little known about why and how neonates discriminate between different classes of stimuli, whereas older pups, which have escaped from the SHRP, and adults appear to respond in a similar manner regardless of the stress-inducing stimulus. Several hypotheses could account for this phenomenon. First, it could simply be a matter of stimulus intensity. Thus, the neonate may be less responsive to stimuli of lower intensities and therefore require a more intense stressor to activate the neuroendocrine cascade that eventually leads to a release of ACTH. Second, it has been well documented that different stimuli activate distinct neural pathways that lead to the release of CRF and thus ACTH. It is conceivable that these neural pathways mature differentially or are activated during development distinctly differently than in adulthood.

A third factor appears to contribute to the reduced capacity of the mother-reared pup to respond to milder stress-inducing procedures. The role of mother's caregiving activities on the developing adrenal was discussed earlier. Evidence shows that maternal factors can also actively inhibit the release of ACTH. Maternally deprived mouse pups show a marked increase in ACTH secretion between 4 and 8 h following removal of the mother. Pups deprived of maternal care for 24 h showed an increase in ACTH following an injection of saline as early as day 6. The effects of maternal deprivation were even more apparent at days 9 and 12. Although in subsequent experiments the response at day 6 was not reliable, significant increases in ACTH were replicated in 9- and 12-day-old neonates. These increases are also observed following 30 min of restraint. In contrast, nondeprived pups failed to show an acute release of ACTH following stress. Whereas feeding was required in order to reduce the sensitivity

Figure 1 Nine-day-old mouse pups during the SHRP: a. plasma corticosterone; b. ACTH. Animals were injected intraperitoneally (IP) 16 and 8 h before testing with the vehicle (polyethylene glycol, $n = 10$), the MR antagonist (MR-A) RU28318 ($n = 15$), or the GR antagonist (GR-A) RU38486 ($n = 15$). Data represent mean $\pm$ SEM. * Significant from vehicle-treated animals, $p < 0.05$. Adapted from Schmidt et al., *Endocrinology* 146(3):1458–1464, with permission. Copyright 2005, The Endocrine Society.

of the adrenal, anogenital stroking can reverse the increased sensitivity of the HPA axis following deprivation. Thus, different components of the mother's behavior appear to be involved in regulating different components of the endocrine stress response. These data suggest that the dam's behavior was actively inhibiting part of the neuroendocrine cascade that ultimately results in the peripheral endocrine responses to stress. Thus the capacity to respond even to mild stimuli is present early in development but is observable only if the maternal inhibitory factors are not present. It is important to note, however, that although the pup can be induced to show an endocrine response to stress during the SHRP, maternal inhibition is not the only rate-limiting factor. If we examine the body of data on the ACTH responses in pups, it emerges that, even when the infant responds to mild stress during the SHRP, the magnitude of the response is always considerably lower in the SHRP than that of the older pups (day 18) and adults.

Stress Hyporesponsive Period and the Brain

The brain is clearly a stress-sensitive organ. It is not the purpose of this article to review all the changes in the brain that have been shown to occur in response to stress in the neonate. For this review, the focus is on the specific neural markers that have a direct effect on the regulation of the pituitary. Several of the early studies reported that during postnatal development there is a deficiency in the neonate's capacity to increase gene transcription and peptide expression of ACTH secretagogues, even though there is a striking increase in ACTH release. However, recent data indicate that this is not completely correct. A mild stressor in the form of a saline injection results in a fast and significant increase of CRF mRNA expression in the PVN in pups during the SHRP within 30 min rather than the 4 h used to demonstrate CRF mRNA in adult animals. There is also clear evidence that CRF is involved in the stress responses during the SHRP. The administration of a CRF antagonist blocked the ACTH response in neonates following exposure to an endotoxin. In addition, recent studies with CRF receptor 1-deficient mice demonstrated that a functioning CRF system at the pituitary level is essential for deprivation-induced changes in corticosterone secretion.

Corticosteroid Feedback

Negative feedback has two modes of operation. First, the proactive mode involves the maintenance

of basal levels of HPA activity and is, in the adult, predominantly mediated by the high-affinity mineralocorticoid receptors (MRs) for corticosterone in higher brain regions. Second, the reactive mode facilitates the termination of stress-induced HPA activity, which also involves the lower-affinity GRs localized in higher brain areas as well as the PVN and the pituitary corticotrophs. Both feedback modes are operative during the SHRP. Early studies reported a pronounced increase of circulating ACTH in response to ADX in neonates, a process that was attributed to the MR. During the SHRP, the MR are highly expressed in the hippocampus, have adultlike properties and, as observed in the adult, have low amounts of corticosterone mainly occupy MRs. However, in a recent study, the treatment of neonatal mice with the MR antagonist RU28318 resulted in only a small increase in circulating corticosterone, indicating a modulatory role of the MRs. In contrast, the GR antagonist RU486 caused a profound increase of ACTH and corticosterone to adultlike levels, indicating that GRs play a predominant role in suppressing the HPA axis activity in the neonate. Because a local blockade of the GRs in the PVN of a neonatal rat resulted only in minor changes of corticosterone secretion, the most likely site of GR-mediated negative feedback in the neonate under basal conditions is in the pituitary.

The reactive feedback, probably mediated by GRs in the brain, seems to be a late-developing process because during neonatal life the stress-induced ACTH levels are not terminated as efficiently as in adulthood. Low levels of GRs are present in the brain around birth; the levels rise slowly and do not achieve adult levels before 4 weeks of age. The affinity of GRs is higher perinatally than at later ages. The microdistribution of GRs changes dramatically in some regions during the first week of life. In some regions of the hypothalamus, GR expression is very dense, but it disappears close to detection levels in later life. Other regions, such as the dentate gyrus of the hippocampus, do not express GRs until day 12.

Twenty-four hours of maternal deprivation impairs the reactive (rather than the proactive) control of HPA activity in the neonates. This was demonstrated in a study design using ADX animals and corticosterone substitution either at the time of ADX or 3 h after ADX, when the removal of the adrenals has triggered a profound ACTH response. The latter condition tests reactive feedback, which appeared during maternal deprivation to be resistant to corticosterone. Corticosterone replacement at the time of ADX, which tests the efficacy of proactive feedback, was not affected by maternal deprivation. The resistance to corticosterone could be due to two interacting

processes. The first represents the hyperdrive of signals from the stress circuitry innervating the PVN neurons triggered by maternal deprivation. The second process may be related to an effect of maternal deprivation on the development of corticosteroid receptors. Indeed, maternal deprivation downregulates hippocampal MR expression as well as GR expression in discrete regions of the hippocampus and the PVN. These changes in GR could be restored if the deprived neonate received aspects of maternal care, such as stroking and feeding. Thus, the altered characteristics clearly may be involved in the impaired feedback following maternal deprivation.

Conclusion

Is there an SHRP? The concept of the SHRP in its most traditional form describes a period in development when most aspects of the HPA axis appear to be downregulated, resulting in an organism that either fails to respond or at best shows a response that is reduced markedly compared to older pups and adults. This may still be applicable to the response of the adrenal if we take total corticosterone as the index of the stress response. Therefore, the SHRP in fact represents an adrenal hyporesponsive period, primarily caused by a potent corticosterone feedback signal that ensures quiescence in the face of common daily stressors. The existing information on the ontogeny of the HPA axis does not support, therefore, the concept of an SHRP as it was formulated in the early 1970s.

<i>Cross-sectional research</i>	Investigations in which all factors are assessed at one time.
<i>Homesickness</i>	Distress from longing for home during one's absence from it.
<i>Life-stage transition</i>	Moving from one life stage to another (e.g., from childhood to young adulthood) with attendant changes (e.g., from being materially dependent on others to becoming more independent).
<i>Prospective/longitudinal research</i>	Investigations in which factors are assessed at more than one time; usually carried out to identify factors that might predict future outcomes.

Pressures facing university students have been a cause of concern because of their impact both on mental health and academic performance. In recent years, student mental health services in the United Kingdom and United States have reported increases in the severity of the presenting problems reported by students. There is also evidence from studies in the United Kingdom that university students report more mental health symptoms than age-matched controls, although there is a lack of information on diagnosable mental disorders in students internationally. In some countries, apparent increases in student distress have been linked to decreases in state funding for students and widening student participation; widening access to higher education has resulted in more diverse student populations, thereby increasing the probability of students in the system with elevated levels of life problems. Given the paucity of information on specific sources of stress and student physical health, the focus in this article is on the stressors associated with the university experience that relate to poor mental health and academic performance.

Conceptual Issues in Student Stress Research

In research on university students, the term stress has commonly been used to describe subjective responses

to an experience or situation. Homesickness and worries associated with meeting course requirements are good examples, although non academic worries are often included. The term has also been used to refer to life events and difficulties such as bereavement or financial hardship that may be considered universally threatening without the proviso in assessment that the event caused stress, upset, or worry. In the main, the literature has emphasized students' subjective worries rather than reports of actual life difficulties. Some authors have argued for the advantages of assessing stress as the amount of subjective worry associated with individual stressors. The individuality in the experience of stress, such as the availability of coping skills and/or personal vulnerability, is recognized by using such a method. The approach is useful for descriptive purposes, but research into the effects of stress on student mental health and achievement demands a more objective assessment of life problems to avoid confounding cause and effect.

The Impact of Commonly Identified Student Stressors

Before reviewing the literature, it should be noted that much of the relevant research has been carried out with narrow samples of students in vocational studies or other specialized subjects. There is therefore the problem of the generalizability of vocational samples, such as medical and nursing students, to the whole student population. The general use of cross-sectional designs, with only one data collection point, is also problematic because causal direction cannot be inferred. The relevant studies described here have therefore been selected because they represent broader populations of university students, and, whenever possible, prospective studies are described.

The sources of stress most commonly identified by students in surveys worldwide include the academic, financial, and relationship domains, although it should be noted that student reports are constrained by the areas initially defined by the investigators. Researchers have also identified the transition to university and paid term-time employment as additional sources of stress. To evaluate the existing evidence of the effects of stress on student mental health and achievement, four of these stressors (transitions, academic and financial pressures, and term-time employment) are discussed here. These have been selected because they are specifically related to the student experience and have been the main focus of investigations into the impact of stress on students.

Transition to University

Becoming a student involves major life changes for young people. Faced with new responsibilities and social roles inherent to the university experience, this transition has the potential to cause distress. The literature has focused on the negative aspects of this transition, but it can also provide the opportunity to learn new competencies and to develop new and rewarding social relationships. For example, longitudinal studies of life-stage transitions have demonstrated their positive effects on self-esteem in young adulthood. However, few longitudinal student studies have been undertaken, and studies that have followed students through the transition to university with a survey before entry are uncommon. Studies that have surveyed students before university entry have shown (usually) short-term increases in mental health symptoms after university entry, which on the face of it appears to be indicative of the stress associated with this experience. In one important study of homesickness, Fisher and Hood measured psychological disturbance in students 3 months before university entry and again 6 weeks into their first term. The levels of psychological disturbance, which included depressive and obsessional symptoms and absent-mindedness, increased in the period after the transition to university. The increases were most apparent in students reporting homesickness, although these students had higher symptom levels to start with. Using an objective measure of residence change, there was no difference in psychological disturbance between students still living with parents and those living on campus. This research demonstrated that, at least in the short term, entering university has consequences in terms of emotional disturbance and cognitive impairment regardless of residence status. This suggests that factors other than the transition of moving from home contribute to student distress.

A subsequent longitudinal study by Andrews and Wilding assessed anxiety and depressive symptoms in students and showed a significant increase in symptoms from 1 month before college entry to midcourse. However, when they looked categorically at the rates of high depression and anxiety in the students, a rather more complex picture emerged. Of the students who were relatively symptom-free before entry, 29% had developed high levels of depression or anxiety symptoms (subsequently explained by factors such as financial hardship and relationship problems). In contrast, approximately one-third of those with high levels of depressive or anxious symptoms before entry were relatively symptom-free by midcourse. This indicates that transitions at this life stage should not be viewed as exclusively negative. There is also a need to consider the more positive aspects of the university

experience and the ways in which they may act to increase student well-being.

Academic Pressures

The university years are a time of continuous assessments for students in most countries, and as such they can put a considerable amount of pressure to achieve on even the hardest of students. As already discussed, one of the problems in assessing the impact of the stress associated with academic work is disentangling cause from effect. Although academic pressures may have a negative effect on emotional well-being, anxiety and depression can affect academic work through symptoms such as high arousal and lack of motivation and concentration. In the absence of in-depth enquiries in this area, it is usually not possible to ascertain whether academic stress is an antecedent or consequence of mental health problems. A more useful line of enquiry into the impact of academic study *per se* is to consider specific academic events such as taking exams. This experience is recognized by leading life events researchers as a universally threatening experience that can increase the likelihood of physical and mental disorders. The effect of studying for and taking examinations has been demonstrated in a recent longitudinal study of undergraduates carried out by Surtees and colleagues at the University of Cambridge in England. Levels of anxiety and depressive symptoms peaked during examination periods, although this suggests that the negative impact is likely to be short-lived for the majority who pass successfully.

Financial Problems

Most young people have not managed their own finances before starting university, and this can often come as a rude shock. Financial hardship is a common problem facing students, and one that is expected to worsen in countries where state funding is being reduced in favor of students paying their own fees and living costs. It is therefore of particular concern that relevant studies have consistently indicated the adverse effects of financial difficulties on student mental health. There is also emerging evidence of the negative impact financial problems and their attendant consequences can have on academic achievement. Much of this research has been carried out in the United Kingdom, where there have been rapid changes to student funding in the past few years.

To address the problems of causality evident in cross-sectional research, Andrews and Wilding recently carried out a longitudinal study of over 350 undergraduate students in different university faculties to consider the impact of different types of stressful life experiences, including financial difficulties. The main

experiences assessed included major financial difficulties, serious personal illness or injury, serious illness and death of close others and serious relationship problems and separations. Of the various adverse experiences, only financial difficulties (experienced by 21%) and personal illness or injury (experienced by 6%) contributed significantly to increased levels of depression midcourse, after adjusting for depressive and anxiety symptoms present before university entry. This initial evidence suggests that the direction of causality is from financial problems to depression. The odds of becoming depressed were three times higher for students with financial problems. This study also considered the impact of stressful life experiences on academic attainment and found that the only adverse experience that predicted poor exam performance was financial difficulties. Depression appeared to mediate this relationship when prior academic attainment was controlled.

Paid Term-Time Employment

An additional stressor related to financial hardship is that of paid work. Large-scale studies have shown that students reporting difficulties in keeping up with bills or having financial problems are significantly more likely to undertake term-time employment. Being obliged to work in addition to full-time study is a further pressure on students. So far, research in this area has focused on the effects of term-time work on academic performance rather than on mental health. Large-scale surveys of university students on both sides of the Atlantic have found that academic performance decreases as the hours of paid work increase. There is evidence from student research in the United States by Pascarella and colleagues that paid term-time work can impede the basic cognitive processes necessary for academic achievement such as reading comprehension and critical thinking. Subsequent studies have found that students who work longer hours during term-time achieve lower end-of-year exam averages than other students. In a recent study, this effect still held after relevant demographic factors and prior academic performance were taken into account.

Implications for Intervention

Student counseling services are a common feature of university life, along with other educational support services and pastoral care from personal tutors and

advisors. However, to our knowledge there is little available information on the systematic evaluation of the effectiveness of such services. Some real-life difficulties that cause students distress may not be amenable to the kinds of services that counselors provide, particularly when they involve financial crises and the pressures of juggling the need to earn money with academic demands. Money management courses would appear to be relevant, but more needs to be known about their availability and effectiveness. Counseling services may be more relevant in dealing with stressors of a more intrapsychic nature. Most services deal with issues of attachment and homesickness, and many provide support in managing the stress experienced by students around exam times. Given the available evidence of the adverse effects of these common problems on student mental health and academic attainment, there is an obvious need for well-controlled trials to evaluate how well university support services deal with different types of student stressors.

Glossary

<i>Allostasis</i>	A sustained adjustment that promotes survival in response to chronic challenge; may increase long-term health burden.
<i>Anovulation</i>	The cessation of ovulation.
<i>Cognitive-behavior therapy</i>	A form of psychoeducation or talk therapy that addresses nonadaptive thoughts, cognitions, attitudes, and conceptualizations.
<i>Eumenorrhea</i>	A normal pattern of menstrual bleeding; can occur in the absence of ovulation.
<i>Gonadotropin-releasing hormone (GnRH)</i>	Decapeptide produced and released in a pulsatile manner from hypothalamic neurons; stimulates the release of pituitary luteinizing hormone (LH) and follicle stimulating hormone (FSH).
<i>Hypothalamic hypogonadism</i>	A condition characterized by suppression of GnRH drive and, in turn, pituitary LH and FSH, resulting in reduced or absent gonadal steroidogenesis and gametogenesis.
<i>Hypothalamic hypothyroidism</i>	An allostatic adjustment in thyroidal function that conserves energy expenditure and is characterized by relatively normal levels of pituitary thyroid stimulating hormone (TSH) in the presence of suppressed levels of thyroid hormones triiodothyronine (T3) and thyroxine (T4).
<i>Limbic-hypothalamic-pituitary-adrenal axis</i>	Neuroendocrine circuit that mediates stress perception and stress responses.
<i>Metabolism</i>	Biochemical processes that regulate energy expenditure and storage.
<i>Secondary amenorrhea</i>	Cessation of menses in a woman of reproductive age who was previously eumenorrheic.
<i>Stress</i>	Physical and psychological stimuli that challenge the status quo and elicit homeostatic or allostatic behavioral responses.

Introduction

A wealth of scientific and clinical evidence supports the notion that stress causes reproductive compromise and increases health burden. Neuroendocrine, metabolic, and behavioral responses to acute stress represent transient homeostatic adaptations that promote survival in the face of perceived challenge; chronic stress elicits allostatic (sustained) adjustments that also promote survival but at greater health cost (Figure 1). Reproductive compromise impedes population replenishment and increases acute and chronic health burden in women, men, and children due to metabolic dysfunction, obesity, diseases of aging, preterm delivery, birth defects, costly and risky infertility therapies, and, through epigenetic mechanisms, it imprints the next generation. Stress is the most common and most commonly underappreciated cause of reproductive dysfunction (Table 1). Stress-induced anovulation (SIA), often termed functional hypothalamic amenorrhea (FHA) or functional hypothalamic chronic anovulation, causes infertility and increases acute and chronic health burden.

Behaviors that chronically activate the limbic-hypothalamic-pituitary-adrenal (LHPA) axis and/or chronically suppress the hypothalamic-pituitary-thyroidal (HPT) axis compromise the hypothalamic-pituitary-gonadal (HPG) axis in both women and men by reducing hypothalamic gonadotropin-releasing hormone (GnRH) drive. Individuals with functional (not due to defined organic conditions) forms of hypothalamic hypogonadism typically engage in a combination of behaviors in response to psychogenic stress that concomitantly induce intermittent or chronic energy imbalance. Further, chronic adrenal activation may increase the energetic cost of common activities such as running. In women, functional hypothalamic hypogonadism exists on a spectrum that includes polymenorrhea (menstrual interval < 24 days), eumenorrhea with reduced luteal progesterone secretion, and anovulatory eumenorrhea, oligomenorrhea (menstrual interval 735 days), or amenorrhea (absence of menstruation for >3–6 months). In men, oligoasthenospermia (very low sperm count with low motility and abnormal morphology) may result, but this is typically not clinically evident unless fertility is being sought or severe testosterone deficiency results in muscle wasting or other phenotypic alterations.

This article focuses primarily on SIA/FHA in women. SIA/FHA typically results from psychogenic stress coupled with a mild energy imbalance and represents an allostatic adaptation, that is, a stable

change in behaviors and secretory patterns that promotes acute survival but at some health cost. SIA/FHA affects roughly 5% of women of reproductive age; less severe forms of hypothalamic hypogonadism are more common and are less clinically evident (Figure 2).

Stress-induced anovulation is theoretically reversible, but reproductive recovery appears to depend on the restoration of eucortisolemia and at least partial recovery from functional hypothalamic hypothyroidism. Hormone replacement strategies have limited benefit for women with SIA/FHA because they do

not promote recovery from allostatic endocrine adjustments in the adrenal and thyroidal axes. Indeed, the rationale for the use of sex steroid replacement is based on the erroneous assumption that functional forms of hypothalamic hypogonadism represent only or primarily a loss of sex steroid exposure due to reduced GnRH drive. Further, the replacement of sex hormones masks deficits that accrue from chronically altered adrenal and thyroidal functions. Long-term deleterious consequences of SIA/FHA probably include an increased risk of cardiovascular disease, osteoporosis, depression, other psychiatric conditions, dementia, and neurodevelopmental compromise in offspring. Although fertility can be restored with exogenous administration of gonadotropins or pulsatile GnRH, fertility management alone does not engender adrenal and thyroidal recovery. Pregnancy in the face of ongoing psychogenic stress and metabolic imbalance may increase the likelihood of poor obstetrical, fetal, or neonatal outcomes. In contrast, behavioral and psychological interventions that address problematic behaviors and attitudes have the potential to facilitate reproductive recovery along with adrenal and thyroidal recovery. In short, full endocrine recovery offers better individual, maternal, and child health.

Figure 2 Continuum of ovarian function in women with preserved menstrual cyclicity. a, Ovulatory eumenorrhea; b, luteal insufficiency; c–d, eumenorrheic anovulation. Pituitary gonadotropin (LH and FSH) and ovarian sex steroid (estradiol and progesterone) levels were obtained daily for one cycle. FSH, follicle-stimulating hormone; LH, luteinizing hormone. Note that $\text{FSH} > \text{LH}$, but $\text{FSH} < 20 \text{ IU/L}$, thus the cause of hypogonadism is hypothalamic rather than reduced ovarian reserve.

Neuroendocrine Mechanisms Linking Cognition, Mood, Behavior, and Gonadotropin-Releasing Hormone Drive

Our conceptualization of the bidirectional interaction between behavior and gonadal function has been refined by scientific insights into the mechanisms mediating neuroendocrine responses to thoughts, feelings, and behaviors.

The proximate cause of hypothalamic forms of hypogonadism, including SIA/FHA, is reduced hypothalamic GnRH input. Gonadal function depends directly on secretion from the hypothalamus of GnRH as pulses. Declines in pulsatile GnRH secretion reduce pituitary secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and wholly or partially compromise folliculogenesis.

Decreased GnRH drive is a common cause of anovulation and amenorrhea. Decrements in central GnRH–LH/FSH drive exist on a continuum, however, and may vary from day to day. Because of this potential variability in GnRH drive, ovarian compromise exists on a spectrum and may present as polymenorrhea, eumenorrhea, oligomenorrhea, or amenorrhea. Clinically, the decreased ovarian function can be occult or obvious. In men, decreased central GnRH drive may cause oligoasthenozoospermia. Typically, gonadal compromise in men is clinically occult unless fertility is sought and the compromise is sufficiently significant to cause infertility. However, severe hypothalamic hypogonadism in men may present as decreased libido, diminished muscle mass, or altered hair (beard) growth.

The most common cause of reduced GnRH drive is functional; that is, it is not due to identifiable organic causes such as hypothalamic tumors or pituitary adenomas. Functional hypothalamic hypogonadism can be defined as a common and theoretically reversible form of gonadal compromise in which psychophysiological responses to life events activate central neural networks and thereby alter glandular secretion and metabolism.

The mechanisms mediating the disruption of central GnRH drive are poorly understood and complex. GnRH neurons are diffusely distributed in the medial basal hypothalamus. Most, but not all, GnRH axons project to the median eminence, allowing pulses of GnRH to be released into the portal vasculature. GnRH neurons communicate with one another via synapses. Although GnRH neurons are endogenously pulsatile, their activity must be synchronized by GnRH-to-GnRH synapses for the GnRH bolus released into the portal vasculature to be of sufficient magnitude to trigger pituitary release of LH and FSH. GnRH neurons receive synapses from neurons that contain GnRH, the endogenous opioid peptide β -endorphin, neuropeptide Y (NPY), and catecholamines. Other factors that modulate the frequency or activity of the GnRH pulse generator are thought to exert their effects indirectly by acting through the neuronal systems that have direct synaptic connections or by interacting with glial cells that interpose between synapses. For instance, progesterone appears to slow the frequency of pulsatile GnRH release by increasing hypothalamic opioidergic tone, but it also may cause glial cells to envelope the GnRH neurons and to reduce thereby the GnRH-to-GnRH connections. Peripheral substances may gain access to the GnRH neuronal network via specialized neurovascular cells that line the fenestrated blood–brain barrier at the level of the hypothalamus and median eminence, so the modulation of GnRH secretion is not

confined to central factors. The brain–gut axis appears to communicate the metabolic status of an individual to the hypothalamic GnRH neurons through multiple mechanisms. A partial list of putative neuromodulators of GnRH drive is shown in [Table 2](#).

Progress has been made in quantifying endocrine patterns for research purposes. However, in humans, GnRH pulsatile secretion can be inferred only from the pattern of LH secretion in the circulation. Blood samples must be obtained via an indwelling intravenous catheter at intervals of 10–15 min for durations of 12–24 h. Even so, inherent limitations exist in estimating GnRH secretion from peripheral LH patterns. The tedious nature of quantifying central GnRH drive explains why this is not done routinely during clinical evaluation. Technical limitations also plague the recognition and quantification of stress and metabolic status. The accuracy of psychometric inventories for assessing and quantifying stress, mood, and cognitive patterns is inherently constrained by reporting biases, whereas endocrine or biophysical indices of stress and metabolic status are technically cumbersome and expensive to collect. Neuroimaging techniques have afforded a new window into the neurochemistry and neuroanatomy of behaviors and thoughts, but these techniques have not yet been used to understand the pathogenesis of stress-induced reproductive compromise.

Although innumerable animal studies have demonstrated that activation of the hypothalamic–pituitary–adrenal (HPA) axis by a variety of stressful paradigms induces reproductive compromise, only a few studies have elucidated the mechanisms mediating the disruption of GnRH drive. Direct evidence exists for corticotropin releasing hormone (CRH), β -endorphin, dopamine, and arginine vasopressin. Recently, NPY has been implicated as serving a neuromodulatory link between metabolic deficits induced by diet and exercise and reduced GnRH drive. A key inhibitory neurotransmitter system in the brain uses γ -aminobutyric acid (GABA). GABA opens the same potassium channels in neurons of the mediobasal

hypothalamus as μ -opioid receptor agonists such as β -endorphin. GABA inhibited GnRH gene expression in rats and suppressed pubertal GnRH increase in juvenile female rhesus monkeys, but the role of GABA in human hypothalamic hypogonadism remains unclear. Serotonin neurons may also play a role in modulating GnRH drive.

Pathogenesis of Stress-Induced Anovulation

The best biochemical evidence supporting the concept that stress impairs ovarian function in women is the consistent demonstration that women with hypogonadotropic hypogonadism not due to defined organic conditions have higher cortisol levels than eumenorrheic, ovulatory women. There is direct evidence that this relationship holds in women with athletic amenorrhea as well. In a study by Loucks et al., an inverse relationship was observed between the degree of ovarian compromise and cortisol levels. When compared with eumenorrheic but sedentary women, eumenorrheic athletes had less luteal progesterone secretion, as evidenced by lower urinary levels of pregnanediol-glucuronide, fewer LH pulses in a day, and higher cortisol levels. Furthermore, amenorrheic athletes that were anovulatory had the fewest LH pulses in a day and the highest cortisol levels despite comparable levels of exertion and fitness. An inverse relationship holds between adrenal activation (independent of the life events or behaviors that initiate or sustain this activation) and suppression of the hypothalamic GnRH drive to the ovary, as evidenced by marked reduction in LH pulse frequency.

Other hypothalamic outputs also are altered in women with SIA/FHA. Given the neuroanatomical integration of the hypothalamus, this is predictable. The purpose of the hypothalamus is to generate an endocrine action plan to preserve the organism in the face of challenge. Part of the action plan involves metabolic mobilization. However, metabolic mobilization involves more than an increase in cortisol secretion. In SIA/FHA, the thyroid axis differs from that of eumenorrheic women in that thyrotropin (TSH) is not increased in response to decrements in thyronine and thyroxine, which indicates an altered hypothalamic set point akin to what is seen in hospitalized patients who develop what is referred to as sick euthyroid syndrome. In athletic women, a similar alteration in the thyroid axis was seen only in those who had compromised ovarian function. The secretory patterns of growth hormone, prolactin, and melatonin also differed from those of eumenorrheic women. The constellation of neuroendocrine aberrations that accompany SIA/FHA strongly suggests that central

neurotransmission has been chronically altered to forge an allostatic state. The aim of allostatic adjustments is to allow the individual to cope with chronic as opposed to acute challenge. In this context, then, the hypothalamus links the external environment, the internal milieu, and gonadal function.

The process of recovering from the allostatic state of SIA/FHA is also interesting but less well documented. We showed that women in the process of recovering from functional hypothalamic hypogonadism displayed cortisol levels identical to those of eumenorrheic women before there was complete recovery of GnRH drive. Further, a marked increase in thyrotropin-stimulating hormone (TSH) drive occurred as a prelude to increases in thyroxine and thyronine. We recently reported that women with SIA/FHA treated with cognitive-behavior therapy (CBT) displayed a return of ovarian function and ovulation and reduced cortisol levels but had only partial recovery from hypothalamic hypothyroidism and no weight gain. These data, coupled with our psychometric data showing that women with SIA/FHA differ from eumenorrheic women (EW) in their attitudes toward eating and desire for thinness, raise the possibility that intermittent or mild energy imbalance may persist after CBT-induced reproductive recovery. In short, hypothalamic recovery involves a set of interlinked readjustments, including LHPA restoration, return of GnRH pulsatility, and at least partial remission of hypothalamic hypothyroidism, but the duration and sequence of recovery is just now beginning to be described and the role of metabolic factors as mediators of recovery remains unclear.

The characteristic hypothalamic alterations associated with SIA/FHA only become problematic when ongoing challenges elicit a chronic rather than acute response. The long-term consequences of persistent HPA activation have been studied in animal models and hippocampal neuron loss has been documented. Stress appears to increase the risk of dementia and other neurodegenerative disorders. Other long-term sequelae of persistent metabolic mobilization are largely unknown, but there is no reason to assume that such a process is benign. For instance, recent data obtained in women with weight-restored anorexia nervosa who remained amenorrheic indicated that exogenous sex steroid replacement was unable to stimulate appropriate bone accretion. The investigators speculated that the ineffectiveness of hormone exposure was due to ongoing metabolic derangements such as increased cortisol exposure, altered growth hormone action, or hypothalamic hypothyroidism. Because of the concomitant endocrine and metabolic disturbances, hypothalamic hypogonadism must be regarded as a condition deserving

clinical attention even when fertility is not an immediate goal.

The central neuromodulators responsible for the initiation and maintenance of the disruption of GnRH are difficult to identify in humans. First, the factors that initiate allostasis may differ from those that maintain allostasis. To study initiating factors, we would need to intensely monitor populations at risk for the development of hypothalamic hypogonadism or try to induce hypothalamic hypogonadism in a nonhuman primate model. Once a chronic hypogonadal state had been reached, it theoretically would be possible to identify the agents that maintain this disruption by administering antagonists that cross the brain–blood barrier, by performing lumbar punctures and obtaining cerebrospinal fluid (CSF), or by performing neuroimaging studies with an appropriate ligand. To date, efforts to identify these neuromodulators in humans have yielded inconsistent results. Thus, naloxone, an opioidergic blocker, increased LH pulse frequency or levels in some, but not all, women with SIA/FHA. Also, the infusion of metoclopramide, a dopamine receptor blocker, to women with FHA accelerated LH pulse frequency, whereas that of eumenorrheic women remained constant. These data suggest that there may be dopaminergic as well as opioidergic inhibition of GnRH drive. To explore the hypothesis that the reduction in GnRH drive was maintained by CRH, vasopressin, β -endorphin, or a combination of these factors, we performed lumbar punctures to obtain rostral CSF in women with SIA/FHA and those with eumenorrhea. This approach revealed increased CRH in the CSF of women with depression, but we found that CRH levels were identical in women with SIA/FHA and eumenorrhea. Vasopressin levels were similar, but, surprisingly, β -endorphin levels were lower in women with SIA/FHA. Further, we evaluated free cortisol in the CSF of these same women and found that these levels were approximately 30% higher in those women with stress-induced anovulation. In aggregate, these findings (Figure 3) support the notion that the preservation of CSF CRH levels in the presence of elevated CSF cortisol reflects chronic stress-induced (allostatic) resistance to negative feedback suppression by cortisol.

Other putative central neurotransmitters that may contribute to the initiation and maintenance of SIA/FHA are the serotonergic and GABAergic systems. Several lines of evidence suggest that serotonergic function gates stress reactivity and metabolism. First, we showed in our monkey model of SIA/FHA that stress-sensitive monkeys had larger cortisol elevations and reduced prolactin responses to fenfluramine, a serotonergic agonist. These data were interpreted as indicating that central serotonergic

Figure 3 Mean $\pm$ SE cerebrospinal fluid hormone levels in eumenorrheic women (EW) and women with SIA/FHA, demonstrating allostatic resistance to cortisol feedback suppression of CRH. a, Cortisol levels; b, CRH levels. CRH, corticotropin releasing hormone; SIA/FHA, stress-induced anovulation/functional hypothalamic amenorrhea. From Brundu, B., Loucks, T. L., Adler, L. J., et al. (2006), Increased cortisol in the cerebrospinal fluid of women with functional hypothalamic amenorrhea, *Journal of Clinical Endocrinology and Metabolism* **91**, 1561–1565.

tone was reduced in stress-sensitive as contrasted with stress-resilient monkeys. Second, serotonergic neurons, which express leptin receptors, terminate on GnRH neurons. Serotonin has satiety effects similar to those of leptin and may modulate the response to orexigenic and anorectic signals. Moenter's lab exposed fasting female mice to saline, leptin, or fluoxetine, a selective serotonin reuptake inhibitor (SSRI) antidepressant, and followed estrus cycle length. Leptin and fluoxetine prevented fasting-induced cycle lengthening, whereas the serotonin receptor antagonist metergoline blocked cycle rescue by fluoxetine. Treating leptin-deficient *ob/ob* and leptin receptor-deficient *db/db* mice with fluoxetine did not normalize body weight or rescue estrus cycles. Further, there is abundant evidence of a role for the serotonergic system in the regulation of stress reactivity and feedback inhibition of the HPA axis by cortisol. In addition, variation in transporter-facilitated uptake of serotonin has been implicated in anxiety in humans and in animal models of anxiety and stressfulness. Human serotonin reuptake transporter (SERT) gene transcription is modulated by a common

polymorphism in its upstream regulatory region. The short variant reduces the transcriptional efficiency of the SERT gene promoter, resulting in decreased SERT expression and serotonin reuptake. The short (s) variant polymorphism is associated with an increased incidence of affective disorders in humans and maladaptive behavior in monkeys coincident with increased HPA responsivity to stress. Further, the long/short genotype produces a phenotype similar to that of the short/short genotype. In humans, the SERT polymorphisms moderated the influence of stressful life events on depression in a representative birth cohort. Stress-sensitive monkeys had a lower expression of SERT mRNA and monoamine oxidase A (MAO-A) in the caudal region of the dorsal raphe nucleus, whereas no differences were detected between stress-sensitive and stress-resilient monkeys in the mRNA for the serotonin 1A autoreceptor or MAO-B. The determinants of stressfulness in women with SIA/FHA are incompletely understood, and this is certainly one of the variables that warrants further investigation.

Judd et al. reported that a single 2 mg dose of alprazolam, a GABA receptor agonist, decreased cortisol levels and increased LH pulse frequency from 0.8 to 2.0 pulses/8 h in women with stress-related anovulation, whereas its administration decreased LH pulse frequency in eumenorrheic women in the follicular phase. These data also suggest a possible indirect role for GABA neurons in the stress-induced neuromodulation of GnRH pulsatility. Not surprisingly, the neurochemistry of stress and SIA/FHA is far from simple, and firm mechanistic conclusions are not possible at present.

Behavioral, Nutritional, and Metabolic Influences on the Reproductive Axis

Identification of factors that activate the adrenal axis and suppress the thyroidal and ovarian axes can be challenging. It has been suggested that different stressors and behaviors activate somewhat different central mechanisms, such that the signals that alter hypothalamic function are specific to the type of stressor. Indeed, this variability may well explain in part why the neurochemistry of stress is so complex. Psychosocial dilemmas are seen as activating those central pathways subserving perception, whereas exercise and weight loss are generally viewed as disturbing metabolic regulation. Although it seems logical that specificity in the neural or peripheral cascades mediating responses to specific stressors exist, we currently have no method for clearly delineating psychogenic from metabolic stress. Psychogenic stress has a metabolic cost and metabolic stressors, such as

food restriction and excessive exercise, are often initiated to cope with psychogenic stress. However, until proven otherwise, the safest assumption is that stress comes in flavors and that some individuals are more sensitive than others to the same stressor or set of stressors.

Behavioral Influences

A number of behavioral and other psychogenic factors including exercise, low weight and weight loss, affective and eating disorders, various personality characteristics, drug use, and external and intrapsychic stresses have been associated with functional hypothalamic hypogonadism. Given individual variation in metabolism, autonomic tone, habitus, aptitudes, attitudes, and psychological valences, what is stressful to one person may be more or less so to another. Therefore, it is not surprising to find behavioral heterogeneity in the pathogenesis of SIA/FHA. Any given stressor, when the dose is large enough, can probably activate the central neural pathways leading to the disruption of GnRH. In clinical research, the trend has been to study single stressors and to partition as separate populations women with exercise amenorrhea, anorexia nervosa, and idiopathic amenorrhea. Populations studied in clinical research settings may not be entirely representative of all women with SIA/FHA because research subjects must meet relatively strict inclusion and exclusion criteria. In general, women with SIA/FHA do not report or do not have an easily identified solitary stressor. Typically, there are multiple, seemingly minor, stressors, such as a combination of job or school pressures, poor eating habits, and increased energy expenditure through activity or exercise.

To understand the role of psychological variables, such as attitudes and expectations, in the pathogenesis of SIA/FHA, we compared three groups of women: those with eumenorrhea and demonstrable luteal adequacy; those with SIA/FHA unrelated to excessive exercise, weight loss, an eating disorder, drug use, or an affective disorder; and those with anovulation due to an identifiable organic cause. Being amenorrheic, regardless of cause, was associated with a compromised sense of psychological equilibrium as reported on psychometric inventories, but, as a group, only women with SIA/FHA differed from the other groups on scales that measured unrealistic expectations and dysfunctional attitudes (defined as attitudes likely to impair coping responses). For instance, women with SIA/FHA were both highly perfectionistic and sociotrophic (having a high need for social approval). Because perfectionism interferes with social approval or acceptance, one interpretation is that the concomitant high drive for perfectionism and sociotrophy

creates an intrapsychic conflict that women with SIA/FHA may not possess the appropriate coping skills to resolve. Another interpretation is that the expectation of simultaneously being perfect and garnering social approval is an unrealistic expectation of self and others. Our earlier study suggested that women with SIA/FHA had trouble relaxing and having fun, attributes that may further predispose them to value performance at the expense of psychological needs. Although women with SIA/FHA do not typically meet the criteria for an eating disorder, they display many attitudes and behaviors similar to women with eating disorders, such as a drive for thinness and disordered eating. What appears to separate women with undifferentiated SIA/FHA from those with an eating disorder is the degree of disturbance, including the degree of food restriction, weight loss, bingeing, and perfectionism. However, direct comparisons have not been conducted for any of these psychological attributes, so these interpretations are based on impressions from extant literature. The bottom line is that attitudes and expectations engender behaviors such as aberrant food intake and excessive exercise that further challenge the hypothalamus to maintain homeostasis. Whether the identifiable behavior is performance pressure, exercise, or irregular food intake, the end result is the same, that is, the disruption of the GnRH pulse generator to the extent that anovulation occurs. It stands to reason, then, that the key to recovery is to change both the behaviors and attitudes that have initiated and now sustain reduced GnRH drive. Once the hypothalamic GnRH pulse generator has been disrupted, it may take a prolonged duration of energy balance and improved psychological equilibrium for the hypothalamic allostasis to reverse and for ovulatory function to return.

The available data suggest that any behavior or expectation that concomitantly activates to a sufficient degree the HPA and HPT axes has the potential to disrupt the GnRH pulse generator. Thus, the list of behaviors and attitudes associated with the development of SIA/FHA is expected to be diverse and extensive. Generally, a mix of multiple, seemingly minor psychogenic and metabolic stressors appears to be more deleterious to reproductive function than a solitary stressor.

Nutritional and Metabolic Influences

Nutritional and metabolic signals play critical roles in the elaboration of homeostatic and allostatic responses to ongoing challenges and can influence the reproductive system at many levels. Research on overnutrition has focused primarily on specifying its effects on gonadal function, with some attention

having been given to the secondary consequences of obesity on endometrial development and central hypothalamic drive. Few studies have characterized the role of nutritional signals in the modulation of reproductive function in men, but available evidence suggests that undernutrition is as deleterious to reproductive competency in men as it is in women.

Metabolic imbalance occurs when energy expenditure exceeds energy intake (negative energy balance). The brain is the most metabolically active tissue in the body, requiring 16 times more energy per unit mass than muscle tissue. Because humans have much bigger brains relative to body size than do other primates or other species, they use more of their daily energy intake than any other species to supply their brain; humans are estimated to use 25%, monkeys 8%, and rodents 5%. Indeed, as a species, humans may be uniquely sensitive to energy imbalance. Metabolism reflects the interactions of the neuroendocrine system (e.g., HPA and HPT axes), body composition (adipokines), and the enteric system (insulin, ghrelin, etc.). Given the multitude of redundant metabolic and nutritional signals communicating energy status to the brain, it is difficult to specify the independent role of any one factor or signal. Signals reflecting energy stores, recent nutritional information, and specific classes of nutrients are integrated in the central nervous system, particularly the hypothalamus, to coordinate energy intake and expenditure. Chronic energy deficiency alters thyroidal function to slow metabolism and correct negative energy balance. Food intake is influenced by availability, emotional state, social cues, and learned behaviors. Although peripheral signals convey information about energy stores and immediate energy availability to the hypothalamus, particularly the arcuate nucleus, these two categories of signals are not exclusive. For instance, leptin and insulin, which are actively transported across the blood-brain barrier, potentiate satiety signals. Thus, the level of any one signal *per se* may be less important than the action of that hormone, and the action is likely to be gated by the constellation of other metabolic signals. Putative orexigenic signals include ghrelin, NPY, orexins A and B, melanin-concentrating hormone (MCH), and agouti-related peptide. Putative anorectic and satiety signals include (but are not limited to) cortisol, CRH, insulin, glucose, resistin, leptin, proopiomelanocortin (POMC), cocaine- and amphetamine-regulated transcript (CART) peptide, peptide YY (PYY), and glucagon-like peptide (GLP)-1. Adipokines (adipocyte-derived hormones) implicated in energy regulation include leptin, adiponectin, and resistin. Leptin is the dominant long-term energy signal informing the brain of adipose

energy reserves; it also functions as a satiety signal. Adiponectin acts as an insulin-sensitizing agent by reducing hepatic glucose production and is reduced in obesity. Resistin is linked to insulin tolerance and decreases glucose uptake by adipocytes. Ghrelin, a 28-amino-acid acylated hormone that is also a growth hormone secretagogue, is produced by the gastrointestinal tract, especially the fundus of the stomach. Plasma ghrelin levels rise during fasting and immediately before anticipated mealtimes and then fall within an hour of food intake, suggesting that ghrelin is important for meal initiation. Given the plethora of nutritional and metabolic signals, specifying their independent effects is challenging, particularly in humans.

Relevant human studies on the role of these factors in reproduction are few. Depression, like stress, involves LHPA axis dysregulation and is associated with loss of appetite; resistin levels correlated with free cortisol levels and adiponectin correlated with insulin sensitivity in a study of depressed humans. In a rodent model, the central LHPA axis challenge of hypoxia and the LHPA axis feedback challenge of dexamethasone independently decreased body weight and increased adiponectin levels, whereas dexamethasone, but not hypoxia, increased resistin. In women, ghrelin levels were reported to be increased in anorexia nervosa and exercise amenorrhea. However, Troisi et al. observed lower ghrelin in women with anorexia or bulimia that correlated with serum cortisol levels. In these studies, subjects and controls differed markedly with regard to body weight and leptin levels, food intake was not assessed, and the diurnal pattern of ghrelin was not determined; for instance, De Souza et al. and Tanaka et al. obtained only a single morning's blood sample after an overnight fast and Misra et al. determined ghrelin levels only overnight. Of note, Miljec et al. reported ghrelin insensitivity in response to an infusion of ghrelin in women with anorexia nervosa compared to eumenorrheic women, but appetite was measured only by self-report and not by food intake. Women with SIA/FHA are more active than most eumenorrheic women and tend to consume less fat and more carbohydrates, but reproductive recovery from SIA/FHA did not require weight gain and was not associated with a change in standard metabolic variables such as leptin.

A balance between energy intake and expenditure is critical to survival. Every action, even thinking, has an energetic cost. Given the fundamental nature of metabolism, it is not surprising that organisms have evolved a complex and redundant signaling system to gate appetite, food-seeking behavior, and fuel storage. Although stress increases energetic demand, the acute behavioral response is often a blunting of

appetite and a reduction in food intake so as to shift attention away from maintenance/sustenance needs and toward coping responses. Chronic reductions of appetite and energy intake in the face of an increase in energy demand probably represent appetite or metabolic allostasis; because of ensuing hypothalamic hypothyroidism, undernutrition may develop without weight loss. The exact mechanisms subserving the multiple associations between reproduction and nutrition and the applicability of animal studies to human syndromes remain to be determined. Given the considerations outlined here, including the high metabolic demands of the human brain, energetic imbalance may have more serious reproductive consequences for humans than for other animals.

Psychological states generate metabolic demands. Psychological states recognized as stressors activate the LHPA axis. When this activation is acute and limited, the adrenal releases a bolus of cortisol, a hormone with multiple metabolic properties. If the stressor is chronic and mild to moderate, then there is modest activation of the LHPA such that cortisol is mildly elevated but the circadian pattern of cortisol is preserved. With extreme unrelenting stress, cortisol secretion is elevated and there is loss of the circadian pattern. Conditions that chronically activate the LHPA axis have been associated with a spectrum of reproductive impairment.

In summary, there is a plethora of metabolic signals that reflect the acute and chronic nutritional state of a given individual. These signals convey information to important tissues and organs and thereby engender homeostatic and allostatic responses. A key target tissue is the brain. Both undernutrition and overnutrition impact reproductive processes. Given the energetic demands of reproductive processes, however, undernutrition has the potential to induce more significant reproductive compromise.

Synergism among Stressors

The notion that stress comes in neurochemical flavors is supported by animal studies suggesting that there are subtle but distinct differences in the neuroendocrine responses to different stress paradigms. Further, neuroendocrine and metabolic responses to acute exercise were greater in men whose HPA axis did not suppress when they were given dexamethasone before the exercise challenge. These data indicate that the degree of HPA activation potentiates the neuroendocrine and metabolic responses to subsequent challenge. Conversely, Altemus et al. showed that lactating women are hyporesponsive to exercise challenge. Taken together, these data buttress the

notion that responses to a given stressor are gated not only by the stressor type but also by host factors, including hormonal and metabolic states. Thus, some individuals are clearly more reactive to similar stressors than others. Obviously, emotional valence and expectations also determine the extent to which psychosocial variables serve as a psychogenic stressors. Our preliminary investigations in women who developed SIA/FHA unrelated to weight loss, exercise, and definable psychiatric disorders indicated that a primary factor that distinguished women with SIA/FHA from those with definable causes of anovulation and those who were ovulatory was the presence of unrealistic expectations. Fioroni also found that women with SIA/FHA, compared to eumenorrheic women or those with other causes of anovulation, held more negative attributions about recent life events. Kirschbaum found that men who did not habituate when exposed to repeated psychogenic challenge viewed themselves as less attractive, had lower self-esteem, and reported being in a depressed mood more often. Apparently, unachievable ambitions or other cognitive distortions create vulnerability to life's inevitable challenges and probably heighten responsivity to metabolic stressors such as exercise or food restriction. Potentially, the converse is true. Energetic imbalance may augment reactivity to psychogenic stressors.

There can be no doubt that weight loss and exercise serve as metabolic stressors. In monkeys trained to run, it was shown that caloric supplementation reversed the anovulation induced by training. Interestingly, the monkeys did not spontaneously develop a compensatory increase in appetite and had to be bribed with colorful candy to consume more calories. On the other hand, modest dietary restriction accompanied by small amounts of exercise greatly increased the proportion of monkeys who become anovulatory when presented with social stress. A prospective study of unselected women demonstrated that exercise and weight loss caused anovulation. It is likely that sufficient exercise and weight loss, independent of psychogenic stress, can alter metabolism to the point that GnRH pulsatility is disrupted. Loucks and Thurma quantified the amount of energy restriction needed to impact GnRH drive by studying eumenorrheic women in the follicular phase. Energy balance was achieved by providing 45 kcal/kg of lean body mass (LBM)/day. Graded daily energy deficits of 10, 25, and 35 kcal/kg were then experimentally induced for 5 days. An energy deficit of 33% had no impact on LH pulse frequency, whereas an energy deficit of approximately 75% induced a decline in LH pulse frequency of approximately 40%. The induction of an energy deficit resulted in a graded increase in the 24-h cortisol level. At an energy

availability of 10 kcal/kg of LBM (75% deficit), the mean 24-h cortisol was increased by approximately 30%, which is the amount of increase typically seen in women with SIA/FHA. Much like stress-sensitive monkeys, women whose luteal phase progesterone levels were lowest at the initiation of the energy restriction showed the greatest response to the imposed metabolic challenge. In most real-life situations, except for extreme circumstances such as war or famine, metabolic deficits are not imposed but, rather, initiated by individuals in response to self-imposed expectations including drive for thinness. Most women with SIA/FHA, when carefully evaluated, display more than one trait, state, or behavior capable of activating stress response cascades or inducing a mild metabolic deficit, but most do not have a profound metabolic deficit that alone would explain the reduction in central GnRH drive. Many of the behaviors, such as exercise, that independently suppress central reproductive drive but only at more extreme levels, may be initiated as coping responses to psychosocial dilemmas. Because of the synergism between metabolic and psychogenic stressors, a combination of multiple, small magnitude, mixed stressors may be potentially more disruptive of reproductive function than a single large stressor limited to one category.

To better understand how a combination of seemingly minor psychogenic and metabolic stressors might synergistically disrupt GnRH drive as demonstrated in our monkey model, we compared endocrine responses to submaximal exercise in women with SIA/FHA to those in eumenorrhea. Women with SIA/FHA displayed a larger increase in cortisol than ovulatory eumenorrheic women in response to exercise. Further, glucose responses between the two groups were divergent in that women with SIA/FHA showed a 10% decrease in glucose whereas eumenorrheic women had a modest 3% increase in glucose, presumably to cope with the energetic demand of exercise. Interestingly, these two groups did not differ at baseline with regard to cortisol or glucose levels. The decrement in glucose seen in SIA/FHA but not eumenorrheic women suggests latent metabolic compromise and indicates that SIA/FHA women are unable to meet energetic demands of ongoing activities. Further, it is likely that the drop in glucose activates the HPA axis and is at least partly responsible for the sustained hypercortisolemia characteristic of SIA/FHA. Because metabolic signals modulate GnRH pulsatility, exercise-induced metabolic imbalance also probably contributes to ongoing reproductive suppression. These results also reveal why the endocrine effects of a stressor, such as exercise, depend on the preexisting neuroendocrine and metabolic state of the individual.

Treatment Considerations

SIA may not be recognized unless the menstrual interval is markedly short, long, irregularly irregular, or absent. Likewise, luteal phase insufficiency due to decreased hypothalamic drive may not be noted unless infertility results. Even then, luteal insufficiency is notoriously difficult to document unless it is recurrent. Based on the foregoing concepts, we speculate that the more clinically evident the ovarian compromise, the greater is the hypothalamic challenge and the more profound are the associated adrenal and thyroidal derangements and sex steroid deprivation.

If a woman with functional hypothalamic hypogonadism is seeking to become pregnant, ovulation induction can be accomplished technically with the exogenous administration of pulsatile GnRH therapy or gonadotropins. The administration of exogenous GnRH therapy is advantageous insofar as it diminishes the risk of ovarian hyperstimulation and multiple gestation associated with gonadotropins. Clomiphene citrate is an option, but it may be less effective because of its hypothalamic site of action and the hypothalamus of women with SIA/FHA is already not responding to decreased sex steroid secretion. Concerns have been raised that ovulation induction may place women with SIA/FHA at increased risk for premature labor and intrauterine growth restriction. The parenting skills of women with SIA/FHA may be impaired because they are already overwhelmed and stressed prior to pregnancy and delivery and their psychological precariousness may place their children at risk for poor psychosocial development. Further, a recent study showed that children born to mothers with clinically occult hypothyroidism due to autoimmune thyroiditis had a mean full-scale intelligence quotient that was seven points lower than the control population. The women with clinically silent hypothyroidism had a 30% reduction in thyroxine, which is roughly what is observed in women with SIA/FHA. Of critical importance is the fact that maternal thyroxine is the only source of fetal thyroxine in the first trimester and the predominant fetal source in the second and third trimesters. Because the fetal brain requires an appropriate amount of thyroxine for neurogenesis, even small deficits in thyroxine may induce neurodevelopmental deficits. Increased maternal cortisol may also have independent effects on fetal neurodevelopment and organogenesis. Recent evidence showed that severe stress, such as that associated with the unexpected death of a child, increased the risk of congenital anomalies of the cranial neural crest eightfold. Further, stress and its endocrine concomitants and even brief undernutrition have been implicated as a cause

of preterm delivery. It is not known if the endocrine concomitants associated with SIA/FHA pose a similar risk, but this is clearly a potential hazard if ovulation induction is undertaken before amelioration of the allostatic changes in the adrenal and thyroidal axes.

A popular approach to a woman with SIA/FHA who is not seeking immediately to become pregnant is to offer her hormone replacement. This approach is based on the presumption that sex steroid deprivation is the primary therapeutic issue. There are inherent limitations with this approach, however. First, data indicate that exogenous sex steroid exposure does not fully promote bone accretion or cardioprotection in the presence of ongoing metabolic derangements. Second, the ongoing insults to the brain from chronic amplification of stress cascades go unchecked. Further, estrogen therapy does not correct hypothalamic hypothyroidism. In short, hormone therapy may mask potentially deleterious processes that are unlikely to be ameliorated by hormone exposure alone. It is critical to remember that SIA/FHA is more than a disorder of reduced GnRH secretion.

Hormone therapy *per se* is unlikely to be harmful, but more than hormone administration is needed – the stress process needs to be interrupted. Although psychopharmacological approaches have not been well studied, they probably could be used on an interim basis in special circumstances. The study by Judd suggested that a short course of alprazolam might be effective in reducing HPA activation and permitting hypothalamic-pituitary-ovarian (HPO) recovery. However, this approach is not recommended for a woman hoping to conceive. The optimal intervention is to reverse the stress process so that the hypothalamus recovers and gonadal function resumes. An integral goal of the treatment plan for women with functional hypothalamic hypogonadism is to help them identify and ameliorate the sources of psychogenic and metabolic stress and to provide emotional support while they learn coping mechanisms other than dieting or exercising. Nonpharmacological interventions such as stress management, relaxation training, or psychoeducation empower individuals by fostering self-care and competency. In this regard, nonpharmacological therapies have the potential to produce long-term benefits on psychological and, thereby, physical health. Behavioral therapies acknowledge the wisdom of the body and understand that SIA/FHA represents an endocrine adaptation that can be reversed with appropriate psychogenic and behavioral modifications.

Given these considerations, we recently studied whether CBT aimed at ameliorating problematic attitudes and behaviors facilitated ovarian recovery in

normal weight women with SIA/FHA. Women with SIA/FHA were randomly assigned to observation versus CBT groups. CBT consisted of 16 visits with a physician, therapist, or nutritionist during 20 weeks. The two groups were followed for return of menses for up to 8 weeks following the intervention. Regardless of menstrual pattern, estradiol and progesterone levels were monitored at weekly intervals for 4 weeks before and after observation or CBT. Approximately 88% of those who underwent CBT had evidence of

ovulation, whereas only 25% of those in the observation group did. **Figure 4** illustrates the recovery of sex steroid secretion in a woman in the CBT group who showed ovarian recovery and in a woman in the observation group who did not have recovery of ovarian function. Interestingly, when it occurred, ovarian recovery was not associated with significant weight gain. This does not mean that subjects did not alter food intake or energy expenditure, however. Improved nutrition generally restores the thyroidal

Figure 4 Serum estradiol and progesterone levels and menstrual bleeding in women with SIA/FHA. a, A patient who was observed and did not recover; b, a patient who was treated with cognitive-behavior therapy and recovered. CBT, cognitive-behavior therapy; SIA/FHA, stress-induced anovulation/functional hypothalamic amenorrhea. From Berga, S. L., Marcus, M. D., Loucks, T. L., et al. (2003), Recovery of ovarian activity in women with functional hypothalamic amenorrhea who were treated with cognitive behavior therapy, *Fertility and Sterility* 80, 976–981.

axis, thereby leading to an increased basal metabolic rate and a need for more calories. Our earlier studies showed that women who experienced a spontaneous recovery from SIA/FHA were eucortisolemic, had increased but not fully restored LH pulsatility, and markedly increased TSH levels in the face of persistent reductions in T_3 and T_4 levels. We recently compared metabolic variables in women who did and who did not recover from SIA/FHA after CBT intervention and observed that ovarian recovery was associated with a decline in cortisol and increase in TSH but that thyroidal hormones and leptin levels were comparable between recovered and unrecovered women. Taken together, these findings suggest that the thyroidal axis, which gates metabolic tone, remains restrained by an as yet uncharacterized factor(s) after HPA and HPO recovery or recovers more slowly than the HPA and HPO axes, similar to the recovery timeline related to acute illness. Ultimately, behavioral and psychological interventions that address problematic behaviors and attitudes permit the resumption of ovarian function along with recovery of the LHPA and HPT axes. In short, full endocrine recovery offers better individual, maternal, and child health.

Summary

Stress is one of the most common and most commonly underappreciated causes of infertility and reproductive compromise in men and women. Stress-induced hypothalamic hypogonadism increases the acute and chronic health burden for individuals and their offspring. Our findings regarding the pathogenesis of SIA/FHA reveal a powerful synergism between metabolic imbalance and psychogenic challenge and underscore that seemingly mundane psychological issues evoke not only reproductive compromise but also concomitant neuroendocrine and metabolic allostasis. These mechanistic pathobiological insights have been harnessed to develop therapeutic options aimed at ameliorating the sustaining cognitive and behavioral variables. By showing that CBT reverses SIA/FHA, we can appreciate the inherent neural plasticity that forms the rationale for coupling mindfulness approaches with the judicious use of psychopharmacological and technical interventions.

Stress Management Training

Essential Hypertension

Angina Pectoris

Myocardial Infarction

Conclusions

Glossary

*Angina
pectoris*

Chest pains, often radiating to the arms, shoulders, and jaw, arising from reduced blood flow to the heart as a result of coronary atherosclerosis.

Angiography

A technique for measuring the extent of coronary atherosclerosis.

Atherosclerosis

An accumulation of fatty deposits causing hardening and narrowing of the arteries.

*Cardiac
rehabilitation*

A combination of lifestyle education, exercise, and, increasingly, stress management training directed at patients suffering from coronary heart disease. The aim of cardiac rehabilitation is to facilitate physical, psychological, social, and emotional recovery.

<i>Essential hypertension</i>	Consistently high blood pressure without any apparent organic or medical cause.
<i>Meta-analysis</i>	Statistical techniques for combining and analyzing the outcomes of several studies.
<i>Myocardial infarction (MI)</i>	Heart attack.
<i>Stress management training (SMT)</i>	A range of techniques with the overall aim of training people to recognize and cope with psychological stress.
<i>Thrombosis</i>	Formation of a blood clot.

Stress Management Training

While stress management training (SMT) denotes a wide variety of practices concerned with improving individuals' recognition of and ability to cope with stress, most of the applications in cardiovascular disease include at least some of the following components: education about the nature of stress and its role in cardiovascular disease; identification of behavioral risk factors and counseling for lifestyle change; relaxation and its application during stress exposure; cognitive restructuring, in which positive and adaptive thoughts and beliefs are substituted for negative and maladaptive ones; and anger and hostility control when thought germane. Generally, SMT programs are undertaken with small groups of patients to maximize efficiency, trade on group motivational processes, and help generate social support.

Essential Hypertension

Essential hypertension is the presence of high blood pressure when there is no detectable medical or organic cause. The vast majority of instances of high blood pressure are of this sort. Hypertension is currently defined as a blood pressure of 140/90 mmHg or greater. Essential hypertension is a substantial problem. It is estimated that as much as 15% of the adult populations of Western countries exhibit high blood pressure, and various epidemiological studies testify that as blood pressure increases, life expectancy decreases, largely from an increased likelihood of stroke and myocardial infarction (MI). Given that psychological stress has been implicated in hypertension and that antihypertensive drugs often have undesirable side effects, SMT emerges as a potential adjunctive or even alternative therapy.

There have been more than 50 publications since the mid-1970s reporting attempts to reduce high blood pressure using some variant of SMT. Considered together, they paint a less than consistent picture. This is perhaps not surprising. First, although some

form of relaxation training characterizes most interventions in this context, other components of SMT are frequently missing. While generalizations are difficult, interventions that have included more SMT components have tended to prove more effective. Second, studies differ in design. Although many have random allocation to SMT and control, control conditions vary between no concerted treatment and carefully engineered attention placebo. SMT appears to fare better compared to minimal interventions than when compared to placebo or active alternative treatments. A meta-analysis by Eisenberg and colleagues concluded that SMT was "superior to no therapy but not superior to credible sham techniques or to self-monitoring alone." (Eisenberg et al., 1993: 964). Third, studies differ in terms of patients' medication status. Results are difficult to interpret when patients are taking antihypertensive medication, since reductions in blood pressure associated with SMT could primarily reflect increased adherence to antihypertensive medication regimens. That may not be a bad thing. Without intervention, hypertensives often show low adherence. Fourth, studies vary in terms of whether they have included follow-up blood pressure assessment, although those that have generally find that gains associated with SMT programs are, to a reasonable extent, maintained at follow-up. Finally, most studies have restricted their outcome measures to resting blood pressure; few have included ambulatory blood pressure assessments during everyday life. Those that have do not uniformly find an advantage for SMT over control treatments.

A serious methodological weakness in virtually all studies to date is the failure to establish a stable baseline blood pressure, by repeated blood pressure determinations, against which to compare the effects of intervention. The phenomenon of white coat hypertension serves to elevate some individual's blood pressure, particularly in clinical settings. The implication of this phenomenon and the failure to establish stable baselines are clear; they are likely to flatter the potential hypotensive effects of interventions. An exception to the usual trend of summary baseline assessment is the study by Johnston and co-workers. Patients were referred to the study by general practitioners if they registered diastolic blood pressure between 90 and 104 mmHg on at least two out of three occasions of measurement. None were taking antihypertensive medication. Prior to allocation to a SMT treatment or an active placebo condition, patients, following training, took their own blood pressures twice daily for 3 months. During this 3-month baseline, blood pressure dropped from referral to start of treatment from 152/98 mmHg to 140/93 mmHg for the SMT group and from 152/98 mmHg to

140/92 mmHg for the control group. Neither SMT nor the control treatment affected any further reductions in blood pressure. SMT and control patients did not differ in follow-up blood pressure or in blood pressure response to a stressful interview. A major implication of this carefully conducted study is that previously reported blood pressure reductions associated with SMT may have reflected adaptation effects. SMT might merely help the process of adaptation to measurement, lowering the blood pressure readings of individuals who are not well adapted to blood pressure measurement procedures. This would render SMT of doubtful clinical significance. Given the importance of the Johnston and colleagues' study, replication is critical. However, it is critical that future studies include prolonged baseline assessment to counter the potentially confounding effects of adaptation to measurement.

Angina Pectoris

Coronary heart disease (CHD) remains the most common cause of death in Western countries for both men and women. The failure of traditional risk factors to provide a complete account of the etiology and course of coronary heart disease has fuelled speculation that other, possibly psychological, factors are involved. Key among these is psychological stress. A frequent expression of coronary heart disease is angina pectoris, experienced as a severe pain in the chest often radiating to the arms, shoulders, and jaw. Angina is a reflection of atherosclerosis of the coronary arteries limiting the supply of circulatory oxygen to the myocardium and, in consequence, reducing the capacity of the heart to deal with increases in load, as, for example, during exercise and psychological stress.

It is therefore surprising that few studies have evaluated the effects of stress management on angina. A notable exception is the Lifestyle Heart Trial. Angina patients were randomly assigned to a lifestyle change intervention or a usual care control group. Among other things, the lifestyle change group patients undertook a fairly comprehensive SMT program, practicing for at least 1 h a day, using the hour-long audiocassette tape provided, for a year. Their data indicate very good compliance. The major outcome measure was the status of patients' coronary arteries as determined by angiography. While there was a worsening of coronary atherosclerosis in the usual care control group over the course of the year, there was evidence of regression of atherosclerosis in the lifestyle change group. However, it is difficult to attribute these impressive gains to SMT, since patients in the lifestyle change condition also switched to a low-fat vegetarian diet and undertook regular vigorous exercise.

Some evidence that SMT may be a key player in these effects comes from the work of Bundy and associates. In the first of two studies, angina patients were assigned either to a comprehensive SMT program lasting 7 weeks or to routine care. Compared to patients receiving routine care, those undergoing SMT reported briefer angina attacks and reduced reliance on medication and showed increased tolerance of exercise, that is, they were able to exercise for a longer period of time before ischemia or pain curtailed their exertions. In a second study, the effects of SMT *per se* were less impressive. Nevertheless, patients who underwent SMT in combination with light exercise fared particularly well. Compared with patients receiving only SMT or usual care, they showed greater exercise tolerance, and compared with patients receiving only exercise or usual care, they registered less frequent angina attacks and were less reliant on medication.

More recently, Lewin and colleagues evaluated the effects of a cognitive-behavioral management program, called the Angina Plan, on psychological adjustment in patients with newly diagnosed angina pectoris. Patients were randomized to receive either the self-help manual (Angina Plan) together with an audio-taped relaxation program or a nurse-led education session, identifying patients' risk factors for CHD, with additional written information. At the 6-month follow-up, patients receiving the Angina Plan demonstrated significantly greater reductions in anxiety and depression, diminished frequency of angina, and fewer physical limitations than patients receiving only the educational session. Although the Angina Plan encompasses SMT techniques, it also consists of a combination of exercise and lifestyle changes. Therefore, it is difficult to attribute the changes demonstrated solely to SMT. However, considered overall, the available data would seem to invite further study of the potential of SMT in controlling angina pectoris.

Myocardial Infarction

Heart attack, or MI, is the most common traumatic consequence of coronary artery disease. It results from blockages in the coronary arteries sufficiently severe to deprive the myocardium of oxygen and damage the muscle to an extent that it ceases to function. MI reflects both atherosclerosis, in which the coronary arteries become narrowed by the formation of fatty deposits or plaques, and thrombosis, the formation of blood clots in the arteries, which serve to fully occlude the already compromised blood flow. However, substantial numbers of patients survive heart attacks, and the widespread administration of

anticoagulant drugs in recent years has increased survival rates substantially. As a consequence, effective cardiac rehabilitation has become an increasingly important health services objective. The overall level of provision has increased markedly in the last 10 years in Western countries. For example, in the UK, surveys reveal that there are now some 300 cardiac rehabilitation programs and that around 30% of major hospitals offer programs. While cardiac rehabilitation was traditionally restricted to basic health education and supervised regular exercise, some form of SMT is increasingly part of the package.

There are sound *prime facie* reasons for including SMT in this context. First, a heart attack is an exceedingly distressing experience for most patients, and levels of depression and anxiety following MI are frequently observed. Second, depressed and anxious cardiac patients are less likely to undertake lifestyle changes, adhere to medication, and exercise, and they also experience greater difficulties in coping with stress. Third, recent evidence indicates that post-MI levels of distress predict subsequent cardiac morbidity and mortality in some, but not all, studies. Fourth, psychological distress appears to be the most important predictor of hospitalization costs following a cardiac event, with distressed cardiac patients accruing four times the cost of nondistressed patients for nonpsychiatric medical interventions.

Early systematic evaluations of cardiac rehabilitation were restricted to programs that were largely exercise based and did not include SMT. Meta-analyses suggest that while such programs had no effects on the recurrence of nonfatal MIs, they were associated with reductions in mortality of 20 to 25%. However, since the studies included in these meta-analyses were generally undertaken with patients who were at low risk for recurrence of MI, the scope for demonstrating benefit was perhaps limited.

Most cardiac rehabilitation programs have included some form of SMT, although, as we shall see, in some instances the provision contains few, if any, of the customary elements of SMT. These have also been subjected to meta-analytic review. Linden and colleagues identified 23 randomized control trials of cardiac rehabilitation programs that contained at least some of the constituents of SMT. In total, these studies afforded data on 2024 patients who had received SMT and 1156 control patients who, for the most part, had received only usual care. The patients given SMT exhibited more substantial reductions in psychological distress, systolic blood pressure, and cholesterol than the controls. Critically, relative to the control condition, SMT was associated with a 40% greater chance of survival during the first 2 years following MI, although not subsequently.

The risk of recurrence of MI was also associated with a substantially reduced risk of MI recurrence.

Since this meta-analysis, four randomized control trials with substantial patient numbers have been published. All four were concerned with alleviating patients' distress following MI. In the Montreal Heart Attack Readjustment Trial (M-Hart), patients' distress was monitored by monthly telephone calls for a year. Those judged to be distressed received a home visit from a nurse who offered emotional support, education, or referral to a general practitioner or cardiologist, as deemed appropriate. Patients in the program were compared to those receiving usual care. The intervention had only minimal effect on distress and no impact on overall survival at 1 year. Indeed, for female patients, cardiac and all-cause mortality tended to be higher in the intervention group. A similar sort of intervention strategy was used by Barr-Taylor and associates and again was compared to usual care. Nurses assessed patients' distress by telephone, and those registering high levels of distress were referred to mental health specialists, although no data were available on how many patients were referred and the nature of any treatment they received. While patients' distress lessened over the 1-year follow-up, there were no group differences. There were insufficient deaths to permit statistical comparison, although the deaths that occurred were split fairly evenly between groups. These two studies have been subject to a number of criticisms. Most importantly, the interventions contained little systematic SMT and, indeed, are barely recognizable as modern cardiac rehabilitation programs. It is likely that they were simply too minimal to influence cardiac health status. Predicated as they were on the reasonable presumption that alleviating patients' distress would yield dividends for recurrence and mortality, the failure of these studies to differentially ameliorate distress makes the absence of significant cardiac health effects unsurprising.

The third SMT intervention also failed to counter patients' distress following MI, again making the absence of effects on cardiac morbidity and mortality entirely predictable. However, the failure of the intervention to alleviate distress in this instance is more difficult to understand. Jones and West randomly allocated 2328 MI patients either to a reasonably comprehensive SMT program or to routine care. The SMT program comprised anxiety reduction techniques, relaxation training, instruction in coping skills, and attempts to promote a more positive adjustment to illness. As indicated previously, there were no differences between groups at 1-year follow-up either in reported distress or in clinical complications and mortality. There are two possible explanations for these

negative findings. First, many patients in the usual care group had good outcomes, which would serve to minimize any advantage for SMT. Second, it is clear that the intervention was not sufficiently powerful to affect psychological change in the most distressed patients. This study suggests, however, that routine psychological screening and intervention may be a useful first step but that more intensive SMT would be required for patients exhibiting extreme emotional distress.

The final randomized controlled trial, Enhancing Recovery in Coronary Heart Disease (ENRICHD), enrolled 2481 patients who had major or minor depression after their MI to receive either cognitive-behavioral therapy (CBT; $n = 1238$), with the option of adjunctive antidepressant medication ($n = 249$), or usual care ($n = 1243$). The main outcome measures were the assessment of depressive symptoms at 6 months, recurrent MI, and all-cause mortality. The intervention consisted of 6 months or less of both individual and group CBT, with variable numbers of sessions per patient. The intervention reduced depression at 6 months but had no significant effect on re-infarction or all-cause mortality, assessed after a mean follow-up of 41 months.

A recent Cochrane review examined the impact of nonpharmacological psychological interventions for adults with CHD (MI, coronary artery bypass graft surgery, percutaneous transluminal coronary angioplasty, angina, and angiographically defined CHD) on all-cause and CHD-related mortality, recurrent cardiac events, and symptoms of anxiety, depression, and stress, compared with adults receiving usual care or no intervention. Thirty-six trials were identified, 18 specifically examining SMT interventions (defined as the use of specific cognitive-behavioral strategies used to help the patient reduce or manage their stress). Of these 18 SMT trials, 11 reported on SMT interventions plus other rehabilitation interventions and seven reported on SMT interventions alone.

Rees and colleagues' systematic review concluded that there was no evidence of any benefit from SMT interventions in reducing all-cause or cardiac mortality. Further, the effects on nonfatal re-infarction were inconclusive. This conclusion was mainly influenced by two large negative randomized controlled trials, one of SMT and the other of CBT. However, trials with a SMT component did demonstrate a reduction in anxiety and depression following intervention. Nevertheless, caution is warranted in interpreting this result, given that it is based on small trials that included a combination of interventions. Accordingly, it is difficult to attribute with certainty such anxiolytic and antidepressive effects to SMT.

Conclusions

Stress management training has now been applied to a number of cardiovascular problems. The largest amount of research attention has been directed toward patients following MI. The data are extremely mixed, and two large trials have yielded disappointing results in terms of cardiological outcomes. Nevertheless, it appears that mixed programs of SMT and exercise rehabilitation produce psychological benefits comparable to those reported for several pharmacological interventions. Further research is required to identify the most effective intervention strategies. It is likely that the greatest dividends will accrue from individually tailored interventions, directing SMT to those patients most in need. Although angina has attracted less study, early indications are that SMT, particularly when combined with exercise, can produce improvements in symptoms and reduce reliance on medication and may even stem atherosclerotic deterioration of the coronary arteries. Finally, the indications for SMT in hypertension are far from compelling. It is possible that SMT acts simply to increase the rate of adaptation to repeated blood pressure measurement.

 Supplements

Glossary

Complementary and alternative medicine (CAM)

The use and practice of therapies and diagnostic techniques that may not be part of any current Western health-care system, culture, or society. The emphasis is on prevention, treatment, or both, using the self-healing capacity within a mind/body approach (in certain but not all cases).

Mind/Body Medicine Strategies

Mind/body medicine is an umbrella term that covers activities and therapies that focus on the self-healing potential within us through the interrelationship of mind and body. The goal in mind/body medicine is to optimize health by combining mental, physical, emotional, and spiritual approaches, which in turn influence the hormonal, nervous, and immune systems.

Yoga, for example, involves both physical movement and a meditative state of mind and may serve to enhance a person's physical stamina and endurance while diminishing the effects of stress and perhaps strengthening one's personal relationship with God or a higher power.

Meditation and Yoga

Meditation can have significant effects on cardiovascular health. In a study conducted at an inner-city health care center, older people with mild hypertension were divided into three groups: those who learned transcendental meditation (TM), a concentration-meditation practice that involves focusing on a single object such as a sound, a word, or short phrase; those who participated in a progressive muscle-relaxation program; and those who were educated in lifestyle changes. At 3 months follow-up, the TM and muscle relaxation groups fared the best in terms of lowered blood pressure, with TM proving to be twice as effective as muscle relaxation.

Using the relaxation response, a simple meditative technique in which the participant sits quietly, focusing on breathing or a word, Harvard's Mind/Body Medical Institute researchers found that 80% of hypertensive patients had lowered blood pressure and decreased medication needs and that 16% were able to discontinue all their antihypertensive medications. These results persisted throughout the 3-year follow-up period. French researchers tested 50 hypertensive people as they sat silently, read, or talked about stress in their lives. Those who talked about stress experienced a sharp increase in systolic blood pressure, an average of 17 mm, an indication that substantiates

further how the mind (thoughts, feelings, and perceptions) can influence our physiology.

Numerous studies have shown that stress is a major trigger for flare-ups of psoriasis, and a study by British researchers suggested that the onset of psoriasis may be influenced by stress as well. Of 64 people with chronic skin problems, including psoriasis, 44 of the participants had experienced a major life event, such as a serious illness or a death in the family, soon before or at about the time their skin eruptions began. A small Johns Hopkins study found that some psoriasis patients who underwent hypnosis and visualized their condition clearing up on its own enjoyed a complete remission of symptoms. In a study of 51 chronic pain sufferers, ranging from back pain to chest pain (angina), a form of mindfulness meditation was used in a 10-week program. Sixty-five percent of patients reported a significant reduction in their perceived pain and 50% said their pain was reduced by more than half. Significant reductions in mood disturbances and psychiatric symptoms accompanied the reduction in pain as well.

Harvard's Mind/Body Medical Institute found that chronic pain patients reduced their physician visits by 36% following implementation of the regular practice of the relaxation response. Equally impressive is that this same technique has been credited for 75% of insomnia patients becoming normal sleepers and 90% having reduced or entirely eliminated sleeping medications.

Guided Imagery

Guided imagery teaches people to imagine scenarios that may help influence certain physiological conditions. Headache sufferers have successfully utilized their imaginations to release the vise grip constraining their face and scalp. Cancer patients have imagined their immune system partnering with their chemotherapy to escort out malignant cells through the lymphatic system. Several pilot studies have demonstrated elevated natural killer cells and elevated levels of serum and salivary immunoglobulin levels following guided imagery interventions. Sufferers of irritable bowel syndrome are taught to envision their digestive tract as healthy and rhythmically producing normal peristaltic contractions to create a harmony between mind and gut and normal evacuation. The University of Arizona's Integrative Medicine/Children's Research Center studies complementary and alternative medicine (CAM) methods of pediatric disorders for which there seems to be no conventional medical therapies available. One study tests the use of relaxation, guided imagery, and chamomile tea in children with recurrent abdominal pain.

Prayer and Spirituality

Prayer and spirituality are recognized CAM therapies by the NIH and funded studies are underway. The University of Michigan is studying the effects of spirituality and religiosity following cardiac surgery. A review of the psychiatric literature revealed 87% of the research that has examined religious involvement as a variable reports a positive effect, with the remaining 13% reporting a negative impact on mental health.

More than 130 controlled laboratory studies show that prayer, or a prayer-like state of compassion, empathy, and love, can bring about healthful changes in many types of living things, from humans to bacteria. This does not mean that prayer always works, any more than drugs and surgery always work, but that, statistically speaking, prayer is effective. Faith helps mobilize a person's defenses and assists in getting well, and optimism generally leads to better outcomes. Many case histories and scientific studies affirm this observation. Oxman and colleagues investigated the role religious feeling and activity played in 232 patients over the age of 55 undergoing cardiac surgery. Those who derived at least some strength, comfort, and hope from religion were more likely to survive longer after cardiac surgery than those who did not. Numerous studies in humans show that we can die as a result of dire beliefs and a sense of overwhelming futility.

Aromatherapy

Aromatherapy is the use of pure essential oils to promote health. Smell is one of the most basic human senses that can evoke a variety of emotions. Aromatherapy can be used in baths, as a diffusion or inhalation, or in massage therapy. Relieving anxiety, reducing stress, and promoting relaxation are perhaps the most well known of the uses for aromatic essential oils. Chamomile is best known for its calming properties. Lemon balm and orange blossom can have profound effects on the reduction of depression and anxiety. Lavender is said to promote a peaceful mood and create a sense of calm. Research around the globe is validating aromatherapy as a medicinal modality. A double-blind, placebo-controlled study in Germany found that oil of peppermint applied to the temples reduced tension and headache pain, perhaps by increasing blood flow to the skin. Aromatherapists believe that the fragrance of oils has a soothing effect on the brain's limbic system, which is involved in memory, emotion, and hormone regulation. Substances that affect mood also affect brain chemistry and the immune system. For example, the essential oil of ylang-ylang, a tropical flower, has been shown to cause the pituitary to

secrete more euphoric endorphins. The scent of oil of marjoram boosts the production of calming serotonin, and oil of grapefruit stimulates the brain to produce natural painkillers called enkephalins. However, critics of aromatherapy suggest that the relaxation attributed to the oils may actually be due to their application by massage, hot baths, the human touch, and other pleasant methods.

Bioenergy Medicine Strategies

This category of complementary modalities is based on the concept that the human energy field is subject to imbalances and that restoration of the energy fields improves health and sleep and promotes relaxation.

Acupuncture

In November 1997, a National Institute of Health panel concluded that acupuncture is an acceptable alternative or adjunct to conventional therapy for headaches, low back pain, fibromyalgia, asthma, and carpal tunnel syndrome. The panel stressed that acupuncture has minimal side effects compared to conventional treatments and noted considerable evidence that acupuncture causes the release of natural pain-relieving substances (endorphins) in the brain. In 1993, an NIH-funded study evaluated the use of acupuncture in the treatment of unipolar depression in 33 women. Based on the results of the small sample, acupuncture appeared to offer significant symptom relief comparable to conventional interventions such as psychotherapy or pharmacotherapy. The use of acupuncture as an effective treatment for depression was substantial enough to warrant a larger-scale clinical trial. Beginning in 1999, the Minneapolis Center for Addiction and Alternative Medicine began exploring the use of electroacupuncture as it pertains to substance abuse, beginning with nicotine and progressing to such substances as heroin and cocaine. Similarly, acupuncture research is being conducted at the University of Arizona. The study will evaluate the use of self-hypnosis, acupuncture, and osteopathic manipulations for children with spastic cerebral palsy.

Therapeutic Touch

Therapeutic touch (TT) is a body energy-field technique in which hands are passed over the body without actually touching to recreate and change energy imbalances for restoring innate healing forces. One of the first studies to be funded by the Office of Alternative Medicine at the NIH monitored the effects of TT on 20 very stressed nursing and medical students facing professional board exams. Students were randomized into two groups: one receiving TT and one receiving no TT. Differences between groups were found to be

significant for IgA, IgM, and apoptosis. Theory building is still needed to explain results that show changes in the immune response to stress-reducing therapies. This study was determined useful in documenting that measurable changes do occur following TT. In a 1986 study on 60 patients with tension headaches, patients who received TT reported an average pain reduction of 70%. The control group receiving mock TT reported an average pain reduction of 37%. Open-heart surgery patients who received TT had lower blood pressure than those who did not. While TT has gained its share of skeptics, the technique is now practiced by an estimated 30 000 health professionals around the world, is offered in at least 200 U.S. hospitals, and is taught in more than 80 universities.

Reiki

Reiki comes from the Japanese word meaning universal life force energy. The practitioner serves as a conduit for healing energy directed into the body or energy field of the recipient with or without physical contact with the body. The vast majority of reports on the effectiveness of reiki appear in popular rather than scientific literature; however, one study showed that reiki can increase hemoglobin and hematocrit levels. The study compared 47 people participating in reiki training and a small control group of 9 healthy medical professionals. The study found a significant increase in the hemoglobin and hematocrit levels among the reiki group and no significant change in the control group.

Manual Healing Strategies

Manual healing strategies is the term used for many body work techniques from both ancient and modern traditions that promote relaxation and treat ailments through reeducation in posture and movement and various forms of bodily manipulations. Acupressure, osteopathy, reflexology, and rolfing, a deep tissue massage used to release fascial adhesions, are just a few of the manual healing strategies that can aid in managing stress-related symptoms.

Massage

Massage therapy includes an array of manual therapies that manipulate the soft tissues of the body in order to reduce anxiety, tension, stress, and depression. In addition, massage therapy increases circulation, controls pain, and promotes a sense of overall well-being. Touch is the main ingredient of massage therapy, which conveys a sense of caring – an important component in the healing partnership. A study of the use of massage in patients with pain from cancer found that those who received massage had a 60% lower level of pain perception and a 24% decrease in

anxiety. More than half reported feeling more relaxed as well. In a study of children and adolescents hospitalized with depression and adjustment disorder, those who were treated with massage were found to be less anxious and depressed than those who viewed relaxation videotapes.

Nutrition, Botanical Medicine and Nutritional Supplements

A healthy diet can help the body's healing system operate more efficiently, as has been demonstrated in a number of clinical research studies. In the 1970s, Dr. Dean Ornish, a medical internist, took the medical community by storm when he suggested that a vegetarian diet (10% fat), combined with yoga, meditation, moderate exercise, and group support, could reverse heart disease. Now clinical studies have demonstrated that once-occluded coronary vessels are functioning optimally, and people subjectively report a return to a healthier, happier lifestyle free from anginal pain. Many third-party payers now cover participation in this lifestyle program to attempt to avoid the more costly coronary bypass surgery and coronary angioplasty. Comparisons of a Western and Eastern lifestyle program in healthy adult subjects showed that those adhering to an Ayurvedic (Eastern) lifestyle similar to the Dean Ornish program visited their physicians less frequently, used fewer prescription medications, and had less episodes of depression than the Western lifestyle group.

Sales of soy-based products such as soy milk, tofu, and tempeh have skyrocketed as a result of reports of their protective effects against breast and prostate cancer and their ability to minimize perimenopausal symptoms. Organic produce rich in natural antioxidants are said to have a positive effect on the nervous system, thus aiding in stress reduction. Coffee substitutes and herbal teas are replacing caffeinated beverages, which contribute to nervousness, anxiety, palpitations, and insomnia. Botanical medicine sales aimed at stress reduction have soared amid claims of safety and less side effects than their pharmaceutical counterparts. The German Commission E, equivalent in many ways to the Food and Drug Administration in the United States, has conducted clinical trials on several botanical medicines for anxiety and mild depression. Kava is derived from the knotty root of a large tropical shrub in the black pepper family. This herb has been widely used in Europe for nervous anxiety, stress, and sleep aid.

Research has demonstrated that kavalactones are responsible for the induced relaxation that acts on the central nervous system. In 1996 in Germany, a double-blind randomized trial investigated the effects

of kava on 58 adults with anxiety. Half the subjects took 100 mg of kava extract (standardized to 70 mg kavalactones) three times per day for a month; the other group took a placebo. After 1 week the kava group showed significant improvement in symptoms compared with the placebo group and continued to improve over the course of the research study. Kava is recommended for short-term use and should not be taken with alcohol, prescription sedatives, or valerian root, a herbal sedative. *Hypericum perforatum*, better known as St. John's wort, is a shrubby perennial plant that, when used in a standardized extract containing the main active component hypericin, improves mood and sleep in those suffering from mild to moderate depression. German researchers are currently studying hypericin, another component of St. John's wort thought to be superior in alleviating mild to moderate depression. The recommended dose is 300 mg three times a day and usually requires at least a month of regular use to achieve maximum symptom management. Following an animal study suggesting that St. John's wort may inhibit alcohol cravings by influencing levels of serotonin and other neurotransmitters, researchers at the University of North Carolina at Chapel Hill are planning a study using the herb on human alcoholics.

Insomnia is one of the most frustrating symptoms associated with stress. Valerian (*Valeriana officinalis*) is a European plant that eases stress and mildly sedates the central nervous system. Valerian binds to the same receptors in the brain as prescription sleeping aids. Even though it is mild compared to pharmaceutical sedatives, valerian is a depressant and should be reserved for occasional use rather than taken nightly. Alcohol and other depressants should be avoided when using valerian root. Chamomile tea is one of the most effective bedtime beverages. This herb has a sedative effect that can be used by all ages. In addition to easing away tensions to help with sleep, chamomile soothes indigestion or heartburn and, for infants, is a helpful remedy for colic.

In addition, there are supplements that aid naturally in the brightening one's mood. Dr. Andrew Weil, from the University of Arizona's Integrative Medicine Program, recommends a simple formula intended to change the balance of neurochemicals in the brain to support energy and mood elevation. In the morning, upon awakening, the amino acid DL-phenylalanine (DLPA) is taken. If sufficient mood elevation has not been achieved after trying DLPA, then L-tyrosine, another amino acid, can be substituted. One may switch back and forth between these amino acids. In addition, vitamins C and B₆, a glass of fruit juice, and a small piece of fruit should be consumed and breakfast eaten 45 min later. Vitamins C and B₆ are

repeated in the evening. These natural supplements appear to be safe to take, even if one is currently on selective serotonin reuptake inhibitor antidepressants. Dr. Weil asserts that aerobic activity is actually the best antidepressant because it increases the production of endorphins, the brain's own opiate-like molecules that are associated with a natural high.

The Hippocampus as a Possible Mediator of the Relationship between Self-esteem, Locus of Control, and Stress

Conclusion: Personality Variables, Brain Structures, and Stress Responses in a Developmental Context

Glossary

Cortisol

A steroid hormone secreted by the human adrenal glands. It is often released in high amounts during periods of stress. High doses lead to interference with the proper functioning of the immune system.

Hippocampus

Seahorse-shaped structure that extends along the inferior horn of each lateral ventricle of the brain and consists of gray matter covered on the ventricular

	surface with white matter. A part of the limbic system, it is involved in the storage of memory for intermediate periods and the consolidation of those memories into permanent form.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The major part of the neuroendocrine system that controls reactions to stress and has important functions in regulating various body processes such as digestion, the immune system, and energy usage. Most species (from humans to simple organisms) share components of the HPA axis. It regulates a set of interactions among glands, hormones, and parts of the mid-brain that mediate the general adaptation syndrome proposed by Selye.
<i>Locus of control</i>	The perception of factors responsible for the outcome of an event. An individual with high internal locus of control believes that his or her own actions caused the outcome. Conversely, an individual with high external locus of control believes the outcome was determined by outside forces.
<i>Personality</i>	The complex of all attributes – behavioral, temperamental, emotional, and mental – that characterize an individual.
<i>Self-esteem</i>	The global value we place on ourselves.
<i>Stressor</i>	Any emotional or physical demand (positive or negative) that gives or results in stress.

The Role of Personality in the Perception of Stress

Lazarus, who has devoted much of his work to the study of stress, noted early on that stressful conditions per se fail to produce reliable effects on task performance. Keeping all situational variables constant, the same stressor can have minimal effect, lead to performance improvement, or result in significant performance impairment across subjects. This led him and others to suggest that individual differences in motivational and cognitive variables are likely to interact with situational components, and what is considered threatening for some, and thus stressful and performance impairing, might be considered as stimulating by others, and thus produce beneficial effects on performance.

Subsequent research identified the process of evaluation as crucial in explaining the impact of psychological variables on the stress response. Any internal or external stimulus is perceived as stressful only if it is evaluated as harmful or threatening. The early notion of the importance of the evaluation has received recent validation with the identification of social evaluative threat as the single most important

factor in determining the stressfulness of a situation in laboratory stress studies.

The Importance of Self-esteem and Locus of Control in the Perception of Stress
